Chapter 1: Patient Care Process

Stuart T. Haines; Mary Ann Kliethermes; Todd D. Sorensen

KEY CONCEPTS

KEY CONCEPTS

①A professional patient care practice is built on three essential elements: a philosophy of practice, a patient care process, and a practice management system.

②A professional patient care practice is predicated on a patient-practitioner relationship established through respect, trust, and effective communication. Patients, and when appropriate, caregivers and family, are actively engaged in decision making.

③Adopting a uniform patient care process—a consistently implemented set of methods and procedures—serves as a framework for each patient encounter, increases quality and accountability, and creates shared language and expectations.

④The patient care process includes five essential steps: collecting subjective and objective information about the patient; assessing the collected data to identify problems and set priorities; creating an individualized care plan that is evidence-based and cost-effective; implementing the care plan; and monitoring the patient over time during follow-up encounters to evaluate the effectiveness of the plan and modify it as needed.

⑤The patient care process is supported by three inter-related elements: communication, collaboration, and documentation. Interprofessional teamwork and information technology facilitate the effective and efficient delivery of care.

⑥A practice management system includes the infrastructure to deliver care. This includes physical space, documentation systems, payment for services, and qualified support personnel.

BEYOND THE BOOK

BEYOND THE BOOK

For an overview of the importance of applying a consistent process of care in practice, listen to the following Pharmacy Forward podcast episodes:

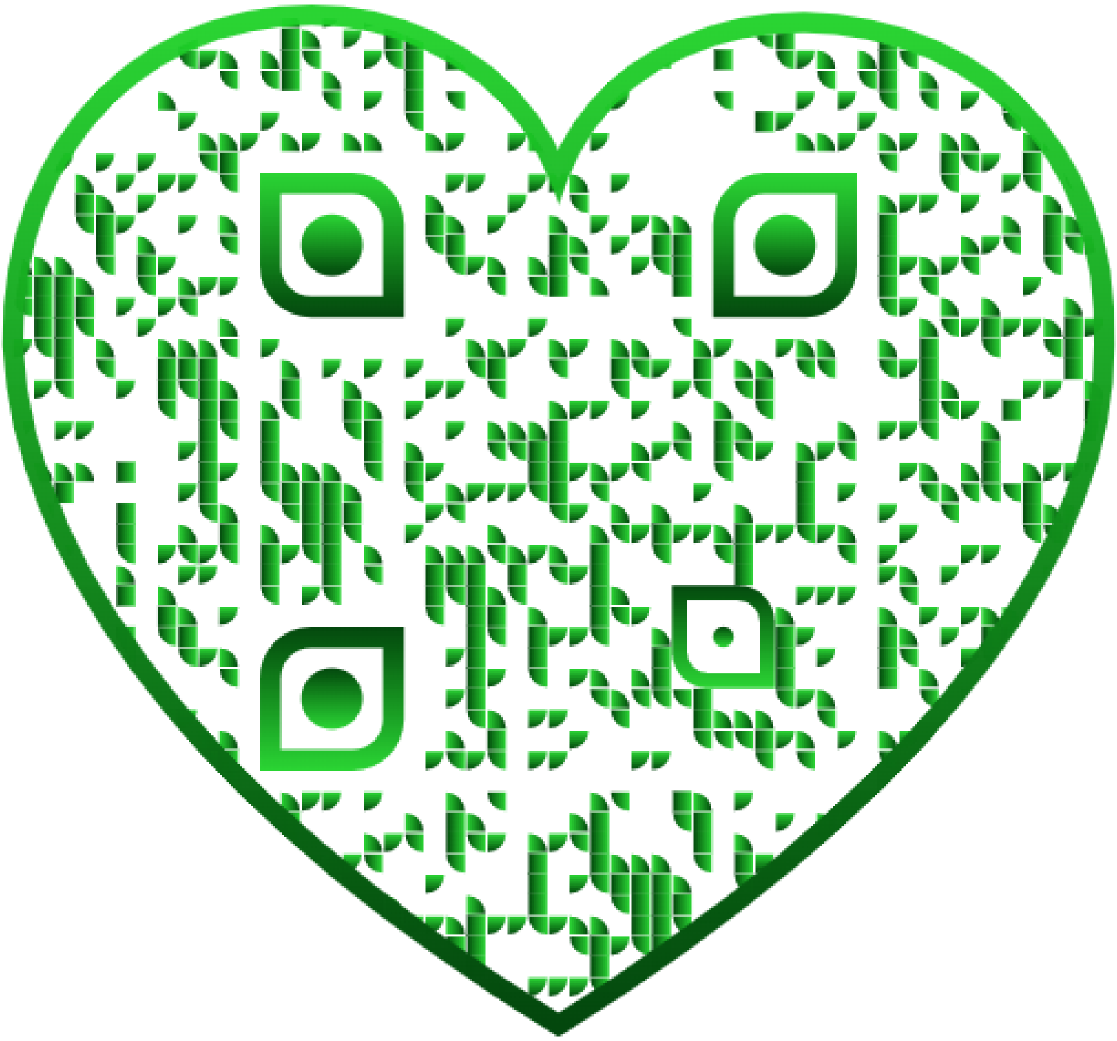
- Pharmacists Patient Care Process – Episode II (Dr. Mary Ann Kliethermes) https://tinyurl.com/y4jp56py

INTRODUCTION

The *patient care process* is a fundamental series of actions that guide the activities of health professionals. All health professionals who provide direct patient care should use a systematically and consistently applied *process of care* in their practice.[1] Until recently, the language to describe the process for delivering comprehensive medication management services was ill-defined. In 2014, the Joint Commission for Pharmacy Practitioners (JCPP)—



representing 11 national pharmacy organizations—endorsed a framework for providing clinically oriented patient care services called the Pharmacist's Patient Care Process.[2] However, the framework and the language to describe the process are not unique to the pharmacy profession. Indeed, medicine, nursing, and dentistry all follow a putatively similar process of care[3] (see Table 1-1). For example, the American Nursing Association (ANA) outlines the nursing process with steps that include assessment, diagnosis, outcomes/planning, implementation, and evaluation.[4] The Academy of Nutrition and Dietetics collapses these general steps into four steps, outlining the nutrition care process to include nutrition assessment, diagnosis, intervention, and monitoring/evaluation.[5] Although the care process is similar across disciplines, each health profession brings a unique set of knowledge, skills, attitudes, and values to the patient encounter.

TABLE 1-1

Professional Standards of Patient Care and Their Domains

Primary Care IPC-2[6,7]	**Dietician's Nutrition Care Process[8]**	**Specialty Nursing: Standards of Practice[9]**	**Physical Therapists[10]**
Symptoms, complaints	Nutrition assessment	Assessment	Examination
Diagnostic screening, prevention	Nutrition diagnosis	Diagnosis	Evaluation
Treatment, procedures, medication	Nutrition intervention	Outcome identification	Diagnosis
Test results	Nutrition monitoring and evaluation	Develop plan of care	Prognosis
Administrative		Implement plan	Plan of care
Other		Co-coordination of care	Reexamination
		Health teaching and promotion	
		Prescriptive authority and treatment	
Diagnoses, diseases		Evaluation	Discharge/Discontinuation summary

Health professionals who provide direct patient care are often called *practitioners*. To *practice* is what health professionals do to bring their unique knowledge and skills to patients. A practice is not a physical location or simply a list of activities. Rather, a professional practice requires three essential elements: (1) a philosophy of practice, (2) a process of care, and (3) a practice management system.[3] These three inter-related concepts make the delivery of patient-centered care possible.

Health professionals have an ethical obligation to promote the health and well-being of the patients they serve. Thus, a philosophy—the moral purpose and a commonly held set of values that guides the profession—is the critical foundation on which the practices of pharmacy, medicine, nursing, and dentistry are built.[11] A philosophy of practice is often formally articulated in the professional code of ethics endorsed by professional organizations and an oath that is recited by members of the profession during rituals and ceremonies. In addition to a code of ethics, most professions have an informal set of beliefs and values that inform self-proclaimed and societal expectations. For example, the concept of *pharmaceutical care* is not formally included in the code of ethics for the profession of pharmacy or the oath of a pharmacist.[12,13] However, informally, pharmacists understand they have a unique responsibility for addressing the drug-related needs of patients and should be held accountable for preventing, identifying, and resolving drug therapy problems.[14] Similarly, dentistry, nursing, and medicine have both formal and informal expectations that guide their professional practice.

A process of care that is systematically and consistently applied during each patient encounter increases the likelihood that optimal health outcomes are achieved.[15] The patient care process used throughout this book includes five essential steps: (1) collecting subjective and objective information about the patient; (2) assessing the collected data to identify problems, determine the adequacy of current treatments, and set priorities; (3) creating an individualized care plan that is evidence-based and cost-effective; (4) implementing the care plan; and (5) monitoring the patient over time during follow-up encounters to evaluate the effectiveness of the plan and modify it as needed (see Fig. 1-1). In addition to the five fundamental steps, a patient-centered approach to decision-making is essential.[16] To be patient-centered requires effective communication and seeking to understand the patient's needs, preferences, and values. It also requires interprofessional collaboration—working with other health professionals to develop and implement a shared plan of care.[17] Each step of the process must be documented. These steps are interdependent, and completing all five steps is necessary to achieve the greatest impact. While the process of care is common to all, each profession has a unique body of knowledge and skills they bring to bear when assessing the data and formulating plans.[3]

A practice must also have a practice management system that supports the efficient and effective delivery of services.[3] Without a well-defined practice management system, the practice would not be sustainable. This includes the infrastructure—the physical, financial, and human resources—as well as policies and procedures to carry out the patient care work. Successful practices have a clear mission statement that defines who the practice serves, the organizational values, and what they hope to accomplish. Furthermore, to achieve its mission, a practice must implement quality improvement methods that measure, evaluate, and improve the actions of practitioners (individually) and the practice (collectively).

While every practice is built on three essential elements—a philosophy of practice, a well-defined patient care process, and a practice management system—the focus of this chapter is to describe the patient care process applied to drug therapy management and explore some environmental issues that are influencing the adoption and application of this process.

IMPORTANCE OF A CONSISTENT PROCESS OF CARE

It is well understood that healthcare is a complex business. Since the turn of the twenty-first century, much effort has focused on gaining control of a disparate, disjointed, costly health system that is not adequately producing desired patient outcomes despite the healthcare workforce laboring harder than ever. Spurred by the Institute of Medicine's *Crossing the Quality Chasm* report from 2001,[18] which set the framework for redesigning healthcare delivery, healthcare institutions and practitioners have embraced the Triple Aim[19] focusing on patient-centeredness, safety, and quality improvement (see Fig. 1-2). The Triple Aim can only be achieved with significant transformations in the delivery of care and by adopting payment models based on value.

FIGURE 1-2

The Triple Aim in healthcare.

To accelerate the requisite redesign of healthcare delivery, the Institute for Healthcare Improvement has developed guiding principles or "rules" for workforces and healthcare communities. Among these principles is to consistently implement what works in order to reduce unnecessary variation. Standardization is important because healthcare systems are embedded in a network of providers in multiple institutions, settings, and practices.[20] A lack of a consistent process of care creates an environment that leads to unacceptable gaps in care. Thus, a process of care must be sufficiently robust to address the complexity that exists among patients and adaptable to varied settings and different acuity levels. For a specific patient care service to be widely adopted and valued, it is imperative that clarity exists both in the execution of care and the terminology used to describe the care.

The stimulus for developing the patient care process for pharmacy was the wide variation observed as pharmacists provided direct patient care, often using the same terminology to describe diverse services or, conversely, the same service is described using different terminology. As patient care services provided by pharmacists, physicians, nurses, and any healthcare practitioner cannot operate in a silo, the services must be clearly articulated and well understood by patients, their caregivers, payers, and other care team members. Without a consistent patient care process, it has been challenging for the pharmacy profession to communicate the pharmacist's role to groups external to the profession and establish the distinct value pharmacists bring to an interprofessional care team. Moreover, the patient must know and understand what is to be delivered and to determine how best to receive the care provided. Likewise, other healthcare team members must determine how best to integrate the pharmacist's work into their efforts caring for the patient.

Structure is essential to maintaining consistency. Systematically implementing a framework for care that is consistently applied assures no important step is overlooked and actions that may lead to greater harm than benefit are reduced or eliminated. Defining a standardized process of care enables data collection for quality assurance and research purposes to demonstrate the value of a service. In the hospital setting, care pathways and standard order sets are examples of standardized care processes that have been used for many years. Creating a standardized patient care process is not intended to reinvent “the wheel” but to create a common framework and language. The process of care described throughout this text provides an easily understood approach that is universally recognized.

PATIENT CARE PROCESS TO OPTIMIZE PHARMACOTHERAPY

There are two aspects that typically differentiate a profession-specific process of care. First, the application of the care process is defined within the context of the profession’s knowledge and expertise. For pharmacy, the patient care process is focused on a patient’s medication-related needs and their experience with medication therapy.[3] Dentists and dental hygienists employ a patient care process focused on a patient’s oral health needs.[21] The nursing care process is applied to provide a holistic approach to a patient’s health needs and include physical and mental health, sociocultural issues, spirituality, as well as economic and lifestyle factors.[4] The general approach to providing care to an individual patient in each of these disciplines is similar; however, the focus of the process is distinct.

The second way in which each profession uniquely addresses a patient’s needs is the manner in which patient-specific information is assessed. When assessing information collected from a patient (eg, history of present illness, physical examination, laboratory data), physicians employ a clinical reasoning process called “differential diagnosis” to weigh the probability of one disease versus other diseases that possibly account for the patient’s signs and symptoms. In the case of dental hygienists, the American Dental Hygienists Association notes that an assessment includes not only a health history and clinical assessment but also a “risk assessment” that includes 11 areas of evaluation.[5] For pharmacists providing comprehensive medication management, the assessment step involves a systematic examination of the indication, effectiveness, safety, and adherence for each of the patient’s medications. This is a unique way of approaching a patient’s health needs. No other discipline applies a systematic assessment process to a patient’s medications and their medication experience in this manner.

Several publications and resources have outlined elements of the patient care process to deliver comprehensive medication management services.[2,11,17,22,23] There is relative consistency between these sources regarding the core elements. What varies is the specificity of the operational definition of each of the process components. Detailed operational definitions help to establish consistency across all practitioners applying the patient care process.[23] This care process is not specific to a care setting—the process can be applied in any setting when providing comprehensive medication management. What often varies is the information collected and its source, as well as the duration of time to complete the process. For example, in an ambulatory care clinic, the patient is often the most important source of information, but in a critical care unit of a hospital, there is a greater reliance on laboratory tests and special diagnostic studies. Similarly, the process of care unfolds in hours or days in acute care settings but may extend over weeks or months in chronic care environments.

Collect Information

When initiating the patient care cycle, a practitioner assures the collection of the necessary subjective and objective information about the patient and is responsible for analyzing the data to understand the patient’s relevant medical needs, medication-related problems, and clinical status. In some cases, this information is directly collected by interviewing the patient or reviewing a medical record. In other cases, the practitioner may rely on other personnel to collect the information to be used in the assessment. This may include a blood pressure determined by a clinical assistant or a list of active medications recorded by a nurse. However, it is ultimately the practitioner’s responsibility to assure that all necessary information is collected and that the data is accurate, regardless of the source. This information is critical to the ability of the practitioner to complete an assessment that will appropriately address all of a patient’s medication-related needs (see Table 1-2).

TABLE 1-2

Collect Patient-Specific Information

Functional Definition[23]

The practitioner assures the collection of the relevant and necessary subjective and objective information about the patient and is responsible for analyzing the data to understand the relevant medical/medication history and clinical status of the patient.

Operational Definition

1. Conduct a review of the medical record to gather relevant information (eg, patient demographics, active medical problem list, admission and discharge notes, office visit notes, laboratory values, diagnostic tests, medication lists).
2. Conduct a comprehensive review of medications and associated health and social history with the patient. The practitioner or team member should:
    - Inquire as to whether the patient has any questions or concerns for the visit.
    - Review social history (eg, alcohol, tobacco, caffeine, other substance use).
    - Review social determinants of health relevant to medication use (eg, whether the patient can afford his/her medications, the patient's education level, housing arrangements, or means of transportation affect his/her ability to use medications as intended).
    - Review past medication history, including allergies and adverse medication effects.
    - Obtain and reconcile a complete medication list that includes all current prescription and nonprescription medications as well as complementary and alternative medicine the patient is taking (eg, name, indication, strength and formulation, dose, frequency, duration, and response to medication).
    - Review the indication for each medication.
    - Review the effectiveness of each medication.
    - Review the safety of each medication.
    - Review the patient's medication experience (eg, beliefs, expectations, and cultural considerations related to medications).
    - Review how the patient manages his/her medications at home (eg, independently or with help, pillboxes, calendars, reminders).
    - Gather any additional information that may be needed (eg, physical assessment, review of systems, home-monitored blood glucose, and/or blood pressure readings).
3. Analyze information in preparation for formulating an assessment of medication therapy problems.

Assess Information and Formulate a Medication Therapy Problem List

Once all of the necessary information to conduct a comprehensive assessment of the patient and their medication-related needs has been collected, the assessment is organized into a problem list consisting of the patient's active medical problems and medication therapy problems. Once identified, problems are prioritized to make decisions regarding the patient's medication therapy to offer the best opportunity to achieve the patient's overall health goals. In doing so, the practitioner reviews each medical condition and medication to make sure that each current medication is *indicated* (or necessary) for the condition for which it is being taken and that each condition that requires drug therapy is being appropriately treated. Then the practitioner determines whether each medication the patient is taking is *effective*, achieving the intended outcome. This includes assuring the medication is the most appropriate option for the patient and is at a dose that is expected to achieve the intended effect. Next, the practitioner considers the *safety* of each medication, assuring that the patient is not experiencing or being exposed to an unnecessary risk of adverse effects or an unintended interaction. Finally, the practitioner then evaluates each medication for *adherence*-related concerns. This includes assuring the patient can take the medication as intended, considering issues such as access and affordability, as well as sufficient knowledge and ability to appropriately administer the medication. Throughout the assessment process, practitioners must keep the patient's goals for therapy at the forefront of their decision-making. Table 1-3 outlines the assessment process applied when optimizing pharmacotherapy.

TABLE 1-3

Assess Patient-Specific Information to Determine Health-Related Needs

Functional Definition[23]

The practitioner assesses the information collected and formulates a problem list consisting of the patient's active medical problems and medication therapy problems to prioritize medication therapy recommendations to optimize medication use and achieve clinical goals.

Operational Definition

1. Assess and prioritize the patient's active medical conditions taking into account clinical and patient goals of therapy.
2. Assess the **indication** of each medication the patient is taking. When assessing the indication of each medication, consider the following:
    - Does the patient have an indication for the medication?
    - Is the medication appropriate for the medical condition being treated?
    - Does the patient have an untreated medical condition that requires therapy but is not being treated or prevented?
3. Assess the **effectiveness** of each medication the patient is taking. When assessing the effectiveness of each medication, consider the following:
    - Is the patient meeting clinical goals of therapy?
    - Is the patient meeting personal goals of therapy?
    - Is the most appropriate drug product being used for the medical condition?
    - Are the dose and duration appropriate for the patient?
4. Assess the **safety** of each medication the patient is taking. When assessing the safety of each medication, consider the following:
    - Is the patient experiencing an adverse event from a medication?
    - Is the dose too high for the patient? Are the frequency and duration appropriate for the patient?
    - Do safer alternatives exist?
    - Are there any pertinent drug-disease, drug-drug, or drug-food interactions?
    - Do additional labs need to be obtained to monitor the safety of the medication therapy?
5. Assess **adherence** and the patient's ability to take (eg, administration, access, affordability) each medication. When assessing adherence, consider the following:
    - Is the patient receiving the most affordable option to optimize adherence?
    - Is the patient able to obtain the medication(s), and, if not, why?
    - Are the medications taken at times during the day that is appropriate to optimize effectiveness and minimize harm but also convenient for the patient?
    - Is the patient taking the medication as prescribed/instructed, or are doses missed? If doses are missed, why?
    - Are the frequency and formulation appropriate for the patient to optimize adherence?
6. Formulate a medication therapy problem list in accordance with the Pharmacy Quality Alliance Medication Therapy Problem Categories Framework.[26]
7. Prioritize the patient's medication therapy problems.

It is critical that the practitioner completes their assessment and defines a problem list considering indication, effectiveness, safety, and adherence *in this order*. This order of assessment ensures that the most relevant issue affecting the patient is identified. For example, there is a great deal of emphasis placed on improving patient adherence to medications, with nonadherence rates reported to range from 28% to 65%.[24,25] However, if a patient is prescribed a medication that is not indicated or is causing an adverse effect, focusing time and attention toward improving medication adherence is misguided and does not address the most important medication therapy problem. Selection of the most appropriate medication for the indication is the primary medication-related need that must be resolved.

The output of the assessment is a medication therapy problem list, prioritized in the order of importance from both the patient's and practitioner's perspectives. Typically, the problem list is framed in a categorical system of medication therapy problems. A nationally recognized system for categorizing the output of a practitioner's assessment is now recognized by the Pharmacy Quality Alliance (see Table 1-4). There are ten medication therapy problem categories, and these align with the four areas of medication use assessment.[26]

TABLE 1-4

Medication Therapy Problem Categories Framework

Medication-Related Needs	Medication Therapy Problem Category
Indication	Unnecessary medication therapy
	Needs additional medication therapy
Effectiveness	Ineffective medication
	Dosage too low
	Needs additional monitoring
Safety	Adverse medication event
	Dosage too high
	Needs additional monitoring
Convenience	Adherence
	Cost

Data from Pharmacy Quality Alliance. Medication Therapy Problem Categories Framework for PQA Measures. Alexandria, VA: Pharmacy Quality Alliance, 2017.

When this assessment approach is applied, a relatively consistent pattern of medication therapy problems emerges.[27-29] The categories identified with the greatest frequency are "needs additional therapy" and "dose too low," followed by "adherence." The other categories are observed less frequently. It should be noted that these reported trends all come from the application of this assessment process in ambulatory care settings. The distribution of medication therapy problems would likely differ in acute care settings.

Develop the Care Plan

Upon completing the assessment and establishing a prioritized list of medication therapy problems, an individualized patient-centered care plan that is evidence-based and as affordable as possible for the patient is created. The plan should be developed in collaboration with the patient or caregiver to meet the patient's expectations and priorities. It should also be developed in collaboration with other healthcare professionals to ensure that all healthcare providers involved with the patient's care agree and support the plan.

The care plan will include goals of therapy and outline contingencies to adjust medications, doses, or delivery, as well as monitoring parameters. It will establish time frames for follow-up and clearly state who will be responsible for each component of the care plan. The steps for developing a patient-centered care plan are outlined in Table 1-5.

TABLE 1-5

Develop the Care Plan

Functional Definition[23]

The practitioner develops an individualized, evidence-based care plan in collaboration with other healthcare professionals and the patient or caregiver that is evidence-based and as affordable as possible for the patient.

Operational Definition

1. Develop a care plan in collaboration with the patient and the patient's healthcare providers to address the identified medication therapy problems.
2. Identify the monitoring parameters important to routinely assess indication, effectiveness, safety, and adherence.
3. Review all medication lists to arrive at an accurate and updated medication list.
4. Determine and coordinate who will implement components of the care plan (ie, patient, pharmacist, other healthcare providers).
5. Determine the type of follow-up needed.
6. Determine the appropriate time frame for patient follow-up.
7. Determine the appropriate mode for follow-up (eg, in person, electronically, by phone).

Implement the Care Plan

Once a care plan is established, the practitioner implements the plan designed to prevent and resolve medication therapy problems. The care plan will likely include activities that the patient and other healthcare providers will be responsible for; however, it is the duty of the practitioner to ensure that each of the elements of the plan has been implemented in a time frame that is reasonable and effective (see Table 1-6).

TABLE 1-6

Implement the Care Plan

Functional Definition[23]

The practitioner implements the care plan in collaboration with other healthcare professionals and the patient or caregiver.

Operational Definition

1. Discuss the care plan with the patient.
2. Ensure patient understanding and agreement with the plan and goals of therapy.
3. Provide personalized education to the patient on his/her medications and lifestyle modifications.
4. Provide the patient with an updated, accurate medication list.
5. Implement those recommendations that you have the ability to implement in your scope of practice.
6. Communicate the care plan to the rest of the care team. If you cannot implement a recommendation(s) on your own, reach a consensus on where implementation is required by another team member.
7. Document the encounter in the electronic health record (eg, a summary of relevant patient information, assessment, and plan, including rationale, monitoring, and follow-up).
8. Arrange patient follow-up.
9. Communicate instructions for follow-up to the patient.

There are many tools and resources that may be used to support a patient and/or their caregivers to successfully implement the care plan. It is in this part of the patient care process where practitioners will employ strategies such as patient education, motivational interviewing techniques, tools that support medication adherence, and patient self-monitoring technologies. These tools and resources are approaches to best meet the needs of the patient and their medication-related goals.

Follow-up with the Patient

After the initial implementation of a care plan, ongoing monitoring and follow-up to evaluate the effectiveness and safety of the plan are essential. The plan should be modified as needed in collaboration with other healthcare professionals and the patient or caregiver. This follow-up process is critical and demonstrates the practitioner has assumed responsibility for the patient's medication-related needs. While a practitioner who serves as a consultant may not follow up to determine if the problem has been resolved, this is inconsistent with the expectations of a comprehensive medication management practice or the patient care process. As a healthcare practitioner who has assumed an important role in a patient's care, it is the responsibility of the practitioner to determine the outcome of drug therapy and take additional action if necessary. This follow-up process can occur through a variety of mechanisms, including face-to-face encounters, phone calls, electronic health record messaging, and telehealth technologies (see Table 1-7).

TABLE 1-7

Follow-Up with the Patient

Functional Definition[23]

The practitioner provides ongoing follow-up and monitoring to optimize the care plan and identify and resolve mediation therapy problems, with the goal of optimizing medication use and improving care.

Operational Definition

1. Provide targeted follow-up and monitoring (eg, in person, electronically, or via phone), where needed, to monitor response to therapy and/or refine the care plan to achieve patient and clinical goals of therapy. Targeted follow-up includes but is not limited to quick check-ins to monitor blood sugar or blood pressure, adjust insulin, check INRs, and provide education.
2. Repeat comprehensive medication management (CMM) follow-up visits at least annually, whereby all steps of the CMM Patient Care Process are repeated to ensure continuity of care and ongoing medication optimization.
3. If the patient is no longer a candidate for CMM, ensure that a plan for continuity of care with other care team members.

The frequency to which follow-up occurs varies from setting to setting. A practitioner practicing in an acute care environment will possibly transfer responsibility for follow-up to other providers, including another pharmacist, when the patient transitions to another setting. In the ambulatory care setting, a practitioner should ensure that a patient has a comprehensive evaluation of their medications and health status annually, at a minimum. In some cases, the nature of the patient's medication therapy problems may be resolved to the degree to which the patient no longer requires ongoing monitoring. In such cases, the patient is referred back to the primary care provider for ongoing follow-up and monitoring.

ENVIRONMENTAL ISSUES

The third critical element of practice is a practice management system. The specifics of any practice management system are based on fundamental business principles and the requirements of the particular type of healthcare setting where the practice exists.[30] In today's healthcare environment, there are essential aspects of managing a practice that practitioners must consider—the metrics to ensure patient health outcomes are being achieved; efficient workflow; communication and documentation using the power of information technology (IT); and data that accurately attributes and values the work each practitioner brings to patient care.

Quality Metrics

Dr. Avedis Donabedian, considered the father of quality improvement in healthcare, defined standards as the desired and achievable performance related to a given parameter—an objective, definable, and measurable characteristic of the structure, the process, or the outcome of the care.[31] To determine quality, there must be a standard to measure the level of quality against. The patient care process sets a standard of achievable performance by defining the parameters of the process that can be measured. With the movement toward outcome-based healthcare models and value-based payment systems, it is critical to objectively measure the impact a patient care service has on a patient's health and well-being. This allows the linkage from the standard process, such as what health problems were identified and how they were addressed during the patient encounter, to the desired outcomes. For the process to be measurable, each element must be clearly defined and performed similarly during each patient encounter. The lack of clarity and consistency has been the Achilles heel in the evidence to support the value of pharmacists' patient care services.[32] The standard process gives pharmacists an opportunity to show value on a large scale because the services are comparable and clearly understood across practice settings.

Workflow, Documentation, and Information Systems

The generation and analysis of data regarding the care provided and the resulting health outcomes are becoming increasingly important not only to organizations but to individual providers as well. Healthcare systems are rapidly embracing the power of technology to analyze information to gain important insights. This technology is only useful if clinical care is robustly documented, collected, and managed. Data is optimally collected as part of the workflow process using IT tools. Creating the requisite tools, however, requires a standard process to build cohesive systems with uniform data sets. Thus, the data elements can be collected using the same collection specifications using different technology systems in different organizations. This allows the reporting of comparable information to providers, payers, and others.

A uniform patient care process sets a standard for the workflow that allows IT systems to capture and extract data for analysis and sharing. Imagine a patient encounter with a practitioner in any setting. The practitioner often has some patient information available before the encounter; however, the practitioner will likely collect new information. This work can now be electronically captured in the collect phase of the workflow. The practitioner will then assess the information and identify new or unresolved medication-related problems. Likewise, this work is captured in the assessment phase of the visit. The practitioner will then update or add to the team's care plan for the patient, and the information can be electronically captured in the planning phase. During the encounter, the practitioner may implement some or all of the plan, and the tasks or services performed are captured during the implementation phase. During the follow-up and monitoring phase, the resolution of identified problems and the response to treatment are documented. The information collected can now be exchanged, extracted, and analyzed at the provider, population, organizational, and payer levels because it is defined and collected in a uniform manner.

The ability to capture clinical data is available through several coding systems (see Table 1-8). The Pharmacy Health Information Technology Collaborative has been at the forefront in assuring pharmacist patient care services are part of the IT systems being developed for the healthcare system in the United States.[33] The collaborative has developed several documents demonstrating how the patient care process is uniformly documented patient care activities and enables sharing of patient-specific information across technology platforms. These data can be used to improve care coordination, workflows, and quality. Examples include documentation templates that use standard technology coding such as the Systematic Nomenclature of Medicine—Clinical Terms (SNOMED-CT) codes that convert a patient care note into an electronically transferable document (eg, pharmacist e-care plan). The information can then be used to document the patient encounter and link patient outcomes attributable to the pharmacist-provided care. The documents are easily accessible on the Pharmacy Health Information Technology (HIT) website (http://pharmacyhit.org/). It is unnecessary for practitioners to know the specific codes or technology structure. However, clinicians should understand how IT operates behind the scenes when performing and documenting their clinical activities. This will enable practitioners to assist information technologists in effectively designing systems that accurately and efficiently capture the elements of the patient encounter that can be used for care coordination, quality metrics, and payment in emerging value-based payment models.

TABLE 1-8

Clinical Coding Systems

System Name	Contents
International Classification of Disease (ICD)	Coding for medical procedures and encounters. The 11th edition was published in 2019.
Systematized Nomenclature of Medicine—Clinical Terms (SNOMED-CT)	A coding system of clinical terminology representing the full scope of clinical information in healthcare.
Logical Observation Identifiers Names and Codes (LOINC)	Vocabulary database of universal identifiers for laboratory and clinical test results.
Healthcare Common Procedural Coding System (HCPCS)	CMS established billing codes for Medicare for medical procedures that include CPT as well as codes not covered by CPT.
Current procedure terminology (CPT)	Coding system for medical procedures developed and maintained by the American Medical Association primarily used for billing services.
RxNorm	Standardized nomenclature for clinical drugs created by the National Library of Medicine.

Documentation, Attribution, and Payment

Payment to healthcare providers for patient care services in the United States has traditionally been based on the documentation and reporting of standard processes of care. Rules and guidance from Medicare and the Centers for Medicare & Medicaid Services (CMS) are considered the billing and payment standard for healthcare providers, both for governmental and commercial payers. Eligible Medicare Part B providers such as physicians, nurse practitioners, and physician assistants must follow standards outlined in the CMS Documentation Guidelines for Evaluation and Management Services.[34] Pharmacists are familiar with these standards because they often use the Subjective, Objective, Assessment, Plan (SOAP) note format when documenting care, including the patient's chief complaint, history of present illness, past medical history, social history, family history, review of systems, physical examination, assessment, and plan. Built on top of the standard documentation requirement is the reporting of the complexity of the care provided. This added layer of documentation is determined by the number of required elements in each documentation domain. A billing code can then be assigned to that patient care encounter which, in turn, equates to a payment commensurate with the level of care provided. While this process is the basis for the current fee-for-service payment structure, it is likely the general format that will remain in any new payment model. Similarly, other providers such as dieticians and physical therapists have standard processes, workflow, and documentation that enable the payment structures in their practice model.

Pharmacists have traditionally used the SOAP note format when documenting care for patients. This is particularly appropriate when providing services incident to an eligible Medicare Part B provider. It is the standard documentation required in that circumstance. However, some elements for the SOAP note, required when using certain billing codes, are not routinely performed by pharmacists (eg, comprehensive physical examination). The pharmacist patient care process establishes a standard framework that reflects the pharmacist's work. Using a standard care process accompanied with a standard documentation framework will result in efficiencies of practice, enable appropriate and accurate billing, and facilitate the attribution of care to desired patient outcomes needed in value-based payment models.

CONCLUSION

A standard process of care provides the structure that all practitioners should follow and, when implemented correctly and consistently, can improve the quality of care provided to patients. It provides a common language that defines roles, responsibilities, and expectations. Comprehensive medication management involves a five-step process: collect, assess, plan, implement, and follow-up. A standard process of care informs the creation of quality metrics and is the foundation of practitioner workflow, the structure of health information systems, and billing for patient care services.

Chapter 19: Contraception

Shareen Y El-Ibiary

KEY CONCEPTS

KEY CONCEPTS

①Unintended pregnancy is a public health issue. A majority of unintended pregnancies occur due to inconsistent use or nonuse of contraceptives.

②Contraception implies the prevention of pregnancy, however, some hormonal contraceptives may also provide noncontraceptive benefits.

③When selecting a contraceptive method consider the following: the effectiveness of the method, its noncontraceptive benefits and adverse medication effects, attitude of the patient and sexual partner toward a contraceptive method, the ability to use it correctly (which may alter its effectiveness), and the ability to pay for the method.

④Patient-specific factors (eg, frequency of intercourse, age, smoking status, desire for return to fertility, concomitant diseases, medications, contraceptive method preference, and medication interactions) must be evaluated when selecting a contraceptive method.

⑤A variety of contraceptive methods are available. Nonhormonal methods include fertility awareness, barriers, spermicides, and the copper intrauterine device. Hormonal methods include progestin-only or combination of estrogen/progestin products.

⑥Adverse effects or difficulties in using the selected method should be monitored carefully and managed in regard to patient-specific factors.

⑦Some medications may alter the effects of hormonal contraceptives or vice versa; therefore, concomitant medications should be assessed for medication interactions with hormonal contraceptives.

⑧Accurate and timely counseling on the management of missed doses is critical for contraceptive effectiveness.

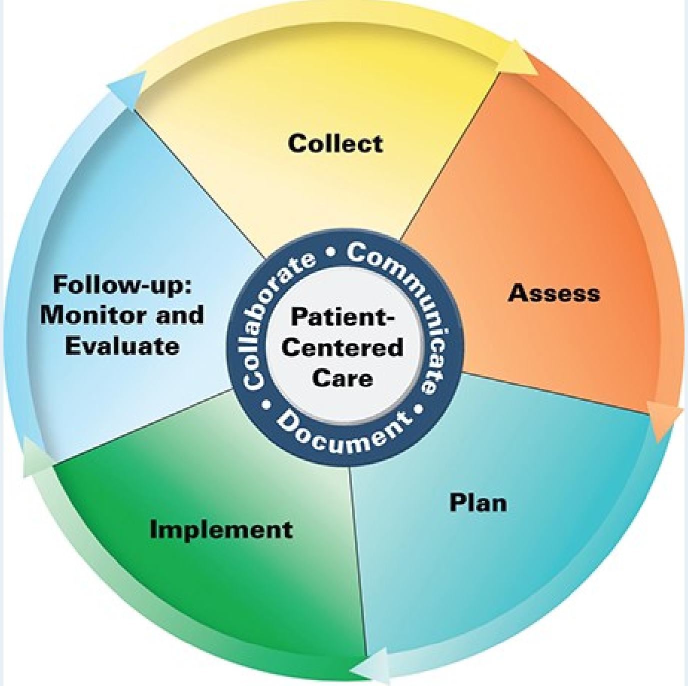
⑨Counseling on the optimal use of the contraceptive method and providing strategies for minimizing sexually transmitted infections/diseases (STIs/STDs) must be provided to all patients being initiated on contraceptives and also for those using contraception on an ongoing basis.

⑩Emergency contraception (EC) may prevent pregnancy after unprotected intercourse or when regular contraceptive methods have failed.

⑪Mifepristone and misoprostol may be used in regimens for medical abortion.

PATIENT CARE PROCESS

Patient Care Process for Contraception



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, date of last menstrual period, pregnant, recently postpartum, breastfeeding, desire for pregnancy/return to fertility)
- Patient medical history (personal and family)
- Medication allergies
- Social history (eg, tobacco/ethanol use, relationships, sexual history)
- Current medications including over-the-counter (OTC), herbal products, dietary supplements
- Previous or current use of contraceptives
- Objective data: blood pressure (BP), height, weight

Assess

- Pregnancy status
- Effectiveness of previous contraceptive methods used (Tables 19-1 and 19-2)
- BP
- Weight and optimal method for use
- Precautions and contraindications to various types of contraceptives utilizing the CDC Medical Eligibility for Contraceptive Use, 2016 (see Table 19-6)
- Venous thromboembolism (VTE) risk factors (eg, recent surgery, plaster casting of lower extremity, cancer, prolonged immobility, recent hospitalization, recently postpartum)
- Medication interactions with various forms of contraception (see Table 19-6 for a select listing of medication interactions)

- Patient ability/willingness to use, adhere, or pay for various forms of contraception (Tables 19-1 and 19-2)

Plan*

- Medication therapy regimen including specific contraceptive dosage forms, dose, route, frequency, and duration (see Table 19-3 for select examples)
- Monitoring parameters including effectiveness and safety (eg, ACHES [abdominal pain, chest pain, headaches, eye problems, and severe leg pain]) (Tables 19-4 and 19-5)

Implement*

- Provide patient education regarding all elements of contraceptive plan (eg, adherence, missed doses, adverse medication effects)
- Schedule appropriate follow-up to assess adverse medication effects, adherence issues, access to contraceptive

Follow-up: Monitor and Evaluate

- Presence of adverse effects (Tables 19-3, 19-4, and 19-5)
- For intrauterine devices (IUD), appropriate placement (eg, checking for strings)
- Changes in medical history (eg, increase in BP, migraines, VTE risk, body mass index [BMI], new medications)
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled "The Menstrual Cycle" (https://www.youtube.com/watch?v=tOluxtc3Cpw) on YouTube from Osmosis. This is a 11-minute video that gives an overview of the menstrual cycle and discusses the cycle phases, ovulation, and the hormones involved. This video is helpful in serving as a quick refresher of the menstrual cycle physiology. Clear understanding of the menstrual cycle is important to understand the mechanisms of action for contraceptive products.

INTRODUCTION

①Unintended pregnancy is a significant public health issue. In the United States, approximately 6 million individuals become pregnant each year.[1] About 45% of pregnancies are unintended, with the highest rates occurring in individuals aged 20 to 24 years, and in individuals aged 15 to 19 when taking into account only sexually active persons.[2] About half of all unintended pregnancies end in abortion, and 41% occur in sexually active couples who claim they used some method of contraception.[2] Education on the use and effectiveness of contraceptive methods must be improved and provided, if the goal of contraception, for all pregnancies to be planned and desired, is to be realized. While cis-women are the primary users of hormonal contraception, these preparations may also be used by transgender individuals, and thus, this chapter is written with this is mind.

EPIDEMIOLOGY

②③Contraception implies the prevention of pregnancy by two methods: first by inhibiting viable sperm from coming into contact with a mature ovum (ie, methods that act as barriers or prevent ovulation) and second, by preventing a fertilized ovum from successfully implanting in the endometrium (ie, mechanisms that create an unfavorable uterine environment). These methods differ in their relative effectiveness, safety, and patient acceptability (Tables 19-1 and 19-2).[3,4]

TABLE 19-1

Pregnancy and Continuation Rates for Various Pharmacologic Contraceptive Methods

Method	Pregnancy Typical Use	Pregnancy Ideal Use	Continuation After 1 Year
Combined and progestin-oral contraceptive	7%	<1%	67%
• Drospirenone-only contraceptive	4%	–	–
Combined hormonal transdermal contraceptive patch			
• Norelgestromin/Ethinyl estradiol	7%	<1%	–
• Levonorgestrel/Ethinyl estradiol	3%	–	–
Combined hormonal vaginal contraceptive ring			
• Etonogestrel/Ethinyl estradiol	7%	<1%	–
• Segesterone/Ethinyl estradiol	3%	–	–
Depo-medroxyprogesterone acetate	4%	<1%	56%
Copper IUD	<1%	<1%	78%
Levonorgestrel IUD	<1%	<1%	80%
Progestin-only implant	<1%	<1%	89%

Data from References 3,5-7.

TABLE 19-2

Comparison of Methods of Nonhormonal Contraception

				Percent of with Pregnancy[a]	
Method	Absolute Contraindications	Advantages	Disadvantages	Perfect Use	Typical Use
Condoms, external (traditionally known as male)	Allergy to latex or rubber	• Inexpensive • STI/STD protection, including HIV (latex only)	• High user failure rate • Poor acceptance • Possibility of breakage	2	13

			• Efficacy decreased by oil-based lubricants • Possible allergic reactions to latex in either partner		
Condoms, internal (traditionally known as female)	• Allergy to polyurethane • History of TSS	• Can be inserted just before intercourse or ahead of time • STI/STD protection, including HIV	• High user failure rate • Dislike ring hanging outside vagina • Cumbersome	5	21
Diaphragm with spermicide	• Allergy to latex, rubber, or spermicide • Recurrent UTIs • History of TSS • Abnormal gynecologic anatomy	• Low cost • Decreased incidence of cervical neoplasia • Some protection against STIs/STDs	• High user failure rate • Decreased efficacy with increased frequency of intercourse • Increased incidence of vaginal yeast UTIs, TSS • Efficacy decreased by oil-based lubricants • Cervical irritation	16	17
Cervical cap (FemCap)	• Allergy to spermicide • History of TSS • Abnormal gynecologic anatomy • Abnormal papanicolaou smear	• Low cost • Latex-free • Some protection against STIs/STDs • FemCap reusable for up to 2 years	• High user failure rate • Decreased efficacy with parity • Cannot be used during menses	9	16[b]
• Spermicides alone • (Phexxi)	Allergy to spermicide	Inexpensive	• High user failure rate • Must be reapplied before each act of intercourse • May enhance HIV transmission • No protection against STI/STDs	16	21-28[c]
Sponge (Today)	• Allergy to spermicide • Recurrent UTIs • History of TSS • Abnormal gynecologic anatomy	Inexpensive	• High user failure rate • Decreased efficacy with parity • Cannot be used during menses • No protection against STIs/STDs	9[d]	14[e]

[a] Failure rates in the United States during first year of use.

[b] Failure rate with FemCap reported to be 24% per package insert.

[c] Failure rate with Phexxi reported to be 27.5% per package insert.

[d] Failure rate with Today sponge reported to be 20% in parous individuals.

[e] Failure rate with Today sponge reported to be 27% in parous females.

Data from References 3,8-10.

HIV, human immunodeficiency virus; STI/STD, sexually transmitted infection/disease; TSS, toxic shock syndrome; UTI, urinary tract infection.

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect failure (eg, patient had an unintended pregnancy). Failure rates are described as perfect-use failure or typical-use failure. A failure in a patient who used the contraceptive agent properly is considered a method failure or perfect-use failure. User failure or typical-use failure rates take into account the perfect-use failure rate plus the user's ability to follow directions correctly and consistently and is usually higher.[3,4] Because the typical-use rate includes both the method and user failure rates, it is used most often.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the normal menstrual cycle hormonal regulation is essential to understanding contraception (Fig. 19-1). The menstruation cycle begins with menarche, usually around age 12 years, and continues to occur in nonpregnant individuals until menopause, usually around age 50 years. Factors such as race, body weight, medical conditions, and family history can affect the menstrual cycle.[3,4] The cycle concludes in the vaginal discharge of sloughed endometrium called *menses* and is comprised of three phases: (1) follicular (or preovulatory), (2) ovulatory, and (3) luteal (or postovulatory).

FIGURE 19-1

The Menstrual Cycle

The first day of menses is referred to as *day 1 of the menstrual cycle* and marks the beginning of the follicular phase[3] which continues until ovulation, which typically occurs on day 14. The time after ovulation is referred to as the *luteal phase*, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but can range from 21 to 40 days. Generally, cycle length variation is greatest in the follicular phase, particularly in the years immediately after menarche and before menopause.[3]

The menstrual cycle is influenced by the hormonal relationships among the hypothalamus, anterior pituitary, and ovaries.[3] The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion[3] which stimulates the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Secretion of FSH and LH directs events in the ovarian follicles that result in the production of a fertile ovum.

Follicular Phase

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development (see Fig. 19-1).[3] Between days 5 and 7, one follicle becomes dominant and later ruptures, releasing the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

Once the follicle has received FSH stimulation, it must receive continued FSH stimulation or it will die.[3] FSH allows the follicle to enlarge and synthesize estradiol, progesterone, and androgen. Estradiol stops the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. It is responsible for increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, it will not survive.

Ovulation

When estradiol levels remain elevated for a sustained period of time, the pituitary releases a mid-cycle LH surge (see Fig. 19-1).[3] This LH surge stimulates the final stages of follicular maturation and ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after the estradiol peak and 10 to 12 hours after the LH peak. The beginning of the LH surge, which occurs about 36 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

Luteal Phase

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the corpus luteum, which synthesizes androgen, estrogen, and progesterone (see Fig. 19-1).[3] Progesterone helps maintain the endometrial lining, which sustains the implanted embryo, maintaining pregnancy. It also inhibits GnRH and gonadotropin release, preventing the new follicle development. If pregnancy occurs, human chorionic gonadotropin prevents regression of the corpus luteum and stimulates continued estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role.

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines.[3] The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, when estrogen and progesterone levels are low, FSH levels start to rise, and follicular recruitment for the next cycle begins.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Contraception

Traditionally, hormonal contraception required breast and pelvic examinations. However, the need for the physical examination may delay contraception access and reinforces the incorrect perception that these methods of contraceptives are harmful. Therefore, in practice, provision of hormonal contraception is followed after a simple medical history, including weight and BP pressure measurement.[5]

③ ④ Most annual preventative medicine visits should include an assessment of and counseling about reproductive health, including contraception and STIs/STDs prevention education. Additionally, other preventive measures, such as pelvic and breast examinations, provision of the human papillomavirus vaccine, and screening for cervical neoplasia, can be accomplished during these visits.

TREATMENT

Desired Outcomes

②The desired goal of all conceptive methods is to prevent pregnancy. However, other health benefits are associated with various contraceptive methods, including prevention of STIs/STDs (with condoms), improvements in menstrual cycle regularity (with hormonal contraceptives), improvements in certain health conditions (with hormonal contraceptives), and management of perimenopause (with hormonal contraceptives).[3]

General Approach to Treatment

Nonpharmacologic Therapy

Fertility Awareness-Based Methods

③④⑤Motivated couples may use fertility awareness-based methods that entail avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. These typically include calendar-based methods such as the standard days or rhythm methods. In addition, there are symptoms-based methods that are based on observed physiologic changes, such as basal body temperature and cervical mucus to determine the fertile period. There are many technology apps available for these methods and the Food and Drug Administration (FDA) approved the first app in this category (Natural Cycles) in 2018.[11] The major drawbacks of these methods are relatively high pregnancy rates and avoidance of intercourse for several days during each menstrual cycle.[3]

Barrier Techniques

③④⑤⑨The effectiveness of barrier methods (eg, condoms, diaphragms, cervical caps, and sponges) depends almost exclusively on the motivation to use them consistently and correctly (see Table 19-2).[3] Their major disadvantage is higher failure rates compared to most hormonal contraceptives; thus, provision of counseling and an advanced prescription for emergency contraception (EC) are recommended for all patients using barrier methods as their primary contraception means.

External condoms (traditionally known as male condoms) create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions, and infectious secretions.[3] Most condoms in the United States are made of latex, which is impermeable to viruses. However, a small proportion are made from lamb intestine, which is permeable to viruses and should not be used to prevent STIs/STDs. Synthetic condoms manufactured from polyurethane are another latex-free option that protect against viruses. Condoms are used worldwide for STIs/STDs protection including human immunodeficiency virus (HIV). When used in conjunction with any other barrier method, their effectiveness theoretically approaches 98%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems. Mineral oil-based vaginal medication formulations (eg, Cleocin, Premarin, and Monistat), lotions, or lubricants can decrease the latex barrier strength and are not recommended, thus water-soluble lubricants (eg, Astroglide and K-Y Jelly) are the preferred choice. Condoms sold with prelubricated spermicides are no longer recommended as they do not provide additional protection against pregnancy or STIs/STDs and may increase vulnerability to HIV.[3,12]

The internal condom (traditionally referred to as the female condom) is a prelubricated, loose-fitting polyurethane sheath which is closed at one end and has flexible rings at both ends.[3] This method protects against viruses, including HIV. Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the vaginal walls. The outer ring remains outside the vagina, covering the labia. The pregnancy rate of the internal condom is higher compared to external condoms. External and internal condoms should not be used together, as slippage and device displacement may occur.

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix to decrease access of sperm to the ovum. The diaphragm must be fitted to the patient for the correct size and requires a prescription.[3] Its efficacy is increased when used in conjunction with a spermicidal cream or jelly. The diaphragm may be inserted up to 6 hours before intercourse and must be left in place for at least 6 hours afterward. However, leaving it in place for more than 24 hours is not recommended due to the potential for toxic shock syndrome (TSS). With subsequent acts of intercourse, the diaphragm should be left in place, and a condom should be used for additional protection.

The cervical cap (FemCap) is a soft, deep cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.[3,8] The cervical cap is available in three sizes, is fitted into the patient for the correct size, and requires a prescription. It should be filled with spermicide prior to use. It should be inserted 6 hours prior to intercourse and not be removed for at least 6 hours after intercourse. It can remain in place for multiple episodes of intercourse without adding more spermicide but should not be worn for more than 48 hours at a time to reduce the risk of TSS. Failure rates with the cervical cap are higher than with other methods. Diaphragms and cervical caps do not protect against some STI/STDs including HIV; thus, condoms should also be used.

Pharmacologic Therapy

Spermicides and Spermicide-Implanted Barrier Techniques

③④⑤⑨Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and act as barriers to prevent sperm from entering the cervical os.[3] They are available as creams, films, foams, gels, suppositories, sponges, and tablets. Spermicides offer no protection against STI/STDs. In fact, when used frequently (more than two times per day), nonoxynol-9 may increase the risk of transmission of HIV by causing small disruptions in the vaginal epithelium.[3,12] The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) do not promote products containing nonoxynol-9 for protection against STIs/STDs.

A new prescription spermicide, marketed as Phexxi, is a combination of lactic acid 1.8%, citric acid 1%, and potassium bitartrate 0.4%, and does not contain nonoxynol-9. The product works to lower pH and reduce sperm motility, and should be used within 1 hour before sexual intercourse and with each act of intercourse. Some precautions include avoiding use in individuals with frequent cystitis as this product has been reported to increase risk.[9]

③④⑤The vaginal contraceptive sponge (Today) contains 1 g of the spermicide nonoxynol-9.[3] It has a concave dimple on one side to fit over the cervix and a loop on the other side to facilitate removal. After being moistened with water, the sponge is inserted into the vagina up to 6 hours before intercourse and provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours but should not be left in place for more than 24 to 30 hours to reduce the risk of TSS. Sponges should not be reused and should be discarded after removal. They come in one size and are available OTC.

The copper IUD (Paragard T380A) contains copper and affects sperm motility to prevent fertilization and implantation (see “Intrauterine Devices" section).

Hormonal Contraception

③④⑤Hormonal contraceptives contain a combination of estrogen and progestin or a progestin alone. Oral contraceptive (OC) preparations first became available in the 1960s, but options have expanded to include transdermal patches, vaginal rings, a long-acting injection, a subdermal implant, and IUDs.

Combined Hormonal Contraceptives

Combined hormonal contraceptives (CHCs) contain both estrogen and progestin and work primarily before fertilization to prevent conception. Progestins provide most of the contraceptive effect by thickening cervical mucus to prevent sperm penetration, slowing tubal motility, delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, to inhibit ovulation, and estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge to prevent ovulation. However, the estrogen's primary role in hormonal contraception is to stabilize the endometrial lining and provide cycle control.[3,4]

Estrogens

The synthetic estrogens found in hormonal contraceptives available in the United States are ethinyl estradiol (EE), estradiol valerate, and more recently estetrol (E4), with EE being the most commonly used.[3,4,13] Most combined oral contraceptives (COCs), including transdermal patches, and vaginal rings contain EE at doses of 20 to 50 mcg, with a few lower than 20 mcg.[4,13,16]

Progestins

Progestin is a term used for a synthetic progesterone and a variety available in the United States. They vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects.[3,4] Their estrogenic and antiestrogenic properties are secondary to the extent their metabolism to estrogenic substances and their androgenic activity depends on the presence of sex hormone (testosterone)-binding globulin (SHBG-TBG) and the androgen-to-progesterone activity ratio. If the amount of SHBG-TBG is decreased, free testosterone levels increase, and their androgenic adverse medication effects are more prominent.[4]

Combined Oral Contraceptives

③ ④ ⑤ With perfect-use, COCs have a 99% efficacy rate, but with typical-use up to 7% of users may become pregnant (see Table 19-1).[3,4] The COCs currently available are modifications of the original products introduced in the 1960s and contain significantly less estrogen and progestin. The older high-dose formulations were associated with vascular and embolic events, cancers, and significant adverse medication effects, but reductions in hormone doses are associated with fewer complications.

Monophasic COCs contain the same amounts of estrogen and progestin for 21 days, followed by a 7-day placebo phase. Multiphasic pills (biphasic, triphasic, or quadriphasic) contain variable amounts of estrogen and progestin for 21 days, also followed by a 7-day placebo phase. Multiphasic and monophasic products are equally effective.[3,14,15] Extended-cycle tablets and continuous combination regimens may offer some benefits for patients in terms of side effects and convenience. With COCs, the types and doses of estrogen and progestin remain constant during the 21 to 24 days that active tablets are taken, though the doses and ratios of estrogens and progestins vary from one preparation to another. The inclusion of three additional days of active pills to shorten the pill-free interval is thought to reduce hormone fluctuation between menstrual cycles. With extended use of COCs, active combination tablets are taken continuously for 84 days or longer followed by 7 days of inactive pills or estrogen-only pills.[4] Table 19-3 lists the available OC products by brand name and specifies hormonal composition.[3,4,7,13,16]

TABLE 19-3

Composition of Commonly Prescribed Oral Contraceptives[a]

Common Brand Names	Estrogen	Micrograms[a] (Number of Days)	Progestin	Milligrams[a](Number of Days)	Spotting and Breakthrough Bleeding by Third Cycle (Up to Tenth Decimal)	Comments
Monophasic Preparations						
Kelnor 1/50	Ethinyl estradiol	50	Ethynodiol diacetate	1	13.9	
Zovia 1/35E, Kelnor 1/35	Ethinyl estradiol	35	Ethynodiol diacetate	1	37.4	
Apri, Cyred, Cyred EQ, Emoquette, Enskyce, Isibloom, Juleber, Kalliga, Reclipsen	Ethinyl estradiol	30	Desogestrel	0.15	13.1	
Azurette, Bekyree, Kariva, Mircette, Pimtrea, Simliya, Viorele, Volnea	Ethinyl estradiol	20 (21) 10 (5)	Desogestrel	0.15	19.7	Contains 2 days of placebo, 5 days of EE 10 mcg only
Nextstellis	Estetrol	14.2 (mg)	Drospirenone	3	N/A	Contains 24 active tablets, 4

						days of placebo Contains estetrol (E4), known to have native estrogen selective actions in tissues, acts as nuclear agonist on vascular system, liver, bone, uterus, and vagina; acts as a membrane antagonist on breast, liver, bone, and vascular system.
Ocella, Safyral, Syeda, Tydemy, Yasmin, Zarah, Zumandimine	Ethinyl estradiol	30	Drospirenone	3	14.5	Safyral and Tydemy are FDA-approved for acne, premenstrual dysphoric disorder (PMDD), and provide folate supplementation, 21 active pills with 0.451 mg of levomefolate calcium and 7 days of 0.451 mg of levomefolate calcium instead of placebos.
Beyaz, Gianvi, Jasmiel, Lo-Zumandimine, Loryna, Nikki, Rajani, Vestura, Yaz[b]	Ethinyl estradiol	20	Drospirenone	3	13.8[c]	Extended cycle—24 active hormone tablets, 4 placebo FDA-approved use for treatment of acne and PMDD Beyaz and Rajani provide folate supplementation, 21 active pills

						with 0.451 mg of levomefolate calcium and 7 days of 0.451 mg of levomefolate calcium instead of placebos
Altavera, Ayuna, Chateal, Chateal EQ, Kurvelo, Levora 0.15/30, Lillow, Marlissa, Portia-28	Ethinyl estradiol	30	Levonorgestrel	0.15	14	
Iclevia, Introvale, Jolessa, Setlakin[d]	Ethinyl estradiol	30	Levonorgestrel	0.15	15.1[c]	Extended cycle—91 tablets (84 active hormone tablets and 7 placebo pills)
Amethia, Ashlyna, Camrese Daysee, Jaimiess, Seasonique, Simpesse	Ethinyl estradiol	30 (84) 10 (7)	Levonorgestrel	0.15	14.3[e]	Extended cycle—91 tablets (84 active hormone tablets and 7 tablets of EE 10 mcg instead of placebos) Considered monophasic since only last 7 days are lower estrogen and act similarly to a placebo
Afirmelle, Aubra, Aubra EQ, Aviane, Balcoltra, Delyla, Falmina, Larissia, Lessina, Lutera, Orsythia, Sronyx, Tyblume, Vienva	Ethinyl estradiol	20	Levonorgestrel	0.1	26.5	Balcoltra contains 7 tables of ferrous bisglycinate instead of placebo
Camrese Lo, LoJaimiess, LoSeasonique	Ethinyl estradiol	20/10	Levonorgestrel	0.1	21.5[e]	Extended cycle—91 tablets (84 active hormone tablets and 7 tablets of EE 10 mcg instead of placebos)
Amethyst, Dolishale	Ethinyl estradiol	20	Levonorgestrel	0.09	N/A[c]	Extended cycle—intended for 1-

						year continuous use available in packs of 28 active pills.
Estarylla, Femynor, Mili, Mono-Linyah, Mononessa, NymyoPrevifem, Sprintec, VyLibra	Ethinyl estradiol	35	Norgestimate	0.25	14.3	
–	Ethinyl estradiol	50	Norgestrel	0.5	N/A	
Cryselle, Elinest, Low-Ogestrel	Ethinyl estradiol	30	Norgestrel	0.3	9.6	
Balziva, Briellyn, Gildagia, Philith, Vyfemla, Wymzya Fe chewable	Ethinyl estradiol	35	Norethindrone	0.4	11	“Fe” contains 7 days of 75 mg ferrous fumarate instead of placebos. “Chewable”—chewable formulation, must drink with 8 oz (~240 mL) of water and rinse mouth.
Necon 0.5/35, Nortrel 0.5/35, Norminest Fe, Wera	Ethinyl estradiol	35	Norethindrone	0.5	24.6	
Alyacen 1/35, Cyclafem 1/35, Dasetta 1/35, Nortrel 1/35, Pirmella 1/35	Ethinyl estradiol	35	Norethindrone	1	14.7	
Generess Fe chewable, Kaitlib Fe chewable, Layolis Fe chewable	Ethinyl estradiol	25	Norethindrone	0.8	19.0	Extended cycle—24 active hormone tablets, 4 days of ferrous fumarate 75 mg instead of placebos “Chewable”—chewable formulation, must drink with 8 oz (~240 mL) of water and rinse mouth.
Aurovela 1.5/30-21, Aurovela 1.5/30-	Ethinyl	30	Norethindrone	1.5	25.2	“Fe” contains 7

28, Aurovela Fe 1.5/30, Blisovi Fe 1.5/30, Hailey Fe 1/20, Gildess Fe 1.5/30, Junel 1.5/30, Junel Fe 1.5/30, Larin 1.5/30, LarinFe 1.5/30, Loestrin Fe 1.5/30, Microgestin 1.5/30, Microgestin Fe 1.5/30	estradiol		acetate			days of 75 mg ferrous fumarate instead of placebos
Aurovela 1/20, Aurovela Fe 1/20, Blisovi 1/20, Hailey Fe 1/20, Junel Fe 1/20, Junel 1/20, Larin (Fe) 1/20, Loestrin 1/20; Fe 1/20, Microgestin 1/20; Microgestin Fe 1/20, Tarina Fe 1/20, Tarina Fe 1/20 EQ	Ethinyl estradiol	20	Norethindrone acetate	1	29.7	"Fe" contains 7 days of 75 mg ferrous fumarate for 7 days. "Chewable"—chewable formulation, must drink with 8 oz (~240 mL) of water and rinse mouth.
Aurovela 24 Fe, Blisovi 24 Fe, Gemmily (capsules), Junel Fe 24, Hailey 24 Fe, Larin 24 Fe, Minastrin 24 Fe chewable, Merzee (capsules), Melodetta 24 Fe (chewable), Microgestin 24 Fe, Tarina 24 Fe, Taytulla (capsules)	Ethinyl estradiol	20	Norethindrone acetate	1	23.2[c]	Extended cycle—24 active hormone tablets, 4 placebo "Fe" contains 4 days of 75 mg ferrous fumarate instead of placebos "Chewable"—chewable formulation, must drink with 8 oz (~240 mL) of water and rinse mouth. Gemmily, Merzee, Taytulla—capsule formulations and also contain 75 mg ferrous fumarate for 7 days, instead of placebos.
Lo Loestrin-24 Fe[b]	Ethinyl estradiol	10	Norethindrone acetate	1	52.0[c]	Extended cycle—24 active tablets, 2 days of EE 10 mcg only and 2 days of 75 mg ferrous fumarate

						tablets

Camila, Deblitane Errin, Heather, Incassia, Jencycla Lyleq, Lyza, Ortho Micronor, Nora-BE, Norlyda, Norlyroc, Orthor Micronor, Sharobel, Tulana	Ethinyl estradiol	–	Norethindrone	0.35 (28)	42.3	Contains 28 days of active tablets, no placebos
Slynd	Ethinyl estradiol	–	Drospirenone	4 (24)	N/A	Contains 24 days of active tablets, 4 days placebo

[a] 28-day regimens (21-day active pills, then 7-day pill-free interval) unless otherwise noted.

[b] Number in parentheses refers to the number of days the dose is received in multiphasic oral contraceptives.

[c] 28-day regimen (24-day active pills, then 4-day pill-free interval).

[d] 91-day regimen (84-day active pills, then 7-day pill-free interval).

[e] Percent reporting after 6 to 12 months of use.

[f] Also contains levomefolate calcium 0.451 mg in all 28 tablets.

Initiating a Combined Oral Contraceptive

⑧COCs may be initiated by different methods, including on the first day of bleeding during the menstrual cycle, or on the first Sunday after the menstrual cycle begins, or using the quick start method. The first day method is when the woman starts the COC on the first day of her menstrual cycle. The patient should be instructed to use a second method of contraception (typically recommend condoms) for at least 7 days after initiation for maximum effectiveness, though some sources state that no backup contraceptive method is required for the first day of menses start method.[13] The "Sunday start" method requires taking tablets on the first Sunday after the menstrual cycle begins and may provide weekends free of menstrual periods.[3,4,10,17] Individuals should also be instructed to use a second method of contraception (typically recommend condoms) for at least 7 days after initiation for maximum effectiveness. It may be preferable to have individuals use additional contraception for the entire first cycle, due to user failure in the first month. In the "quick start" method, the patient takes the first tablet on the day of her office visit. Patients should be instructed to use a second method of contraception for at least 7 days and potentially until she begins her next menstrual cycle to ensure optimal effectiveness. Patients should be informed that the menstrual period will be delayed until completion of the active tablets in the current OC pack. This method is more successful in getting individuals to start OCs and to continue using OCs through the third cycle of use.[3] The CDC recommends that individuals start or resume hormonal contraception no sooner than 5 days after use of the emergency contraceptive ulipristal acetate to maximize the effectiveness of both products (use of the two products together may decrease effectiveness). Long-acting reversible contraception (LARC) methods such as the IUD and implant, however, can be started at the time of ulipristal acetate use.[10,17]

Selecting a Combined Oral Contraceptive

④⑤③Because all COCs are similarly effective in preventing pregnancy (see Table 19-1), the initial choice is based on the hormonal content and dose, preferred formulation, and coexisting medical conditions (see Table 19-6).[4,16,17] In individuals without coexisting medical conditions, an OC containing 35 mcg or less of EE is recommended (see Table 19-3).[4,7,13,16] This strategy is based on evidence that complications and side effects of CHC (ie, VTE, stroke, or myocardial infarction [MI]) result from excessive hormonal content. With nonadherence to OCs, the risk of pregnancy may be greater in individuals taking COCs containing less than 35 mcg of EE. Individuals with oily skin, acne, or hirsutism should be given low androgenic COCs.[4] Choice of an agent based upon coexisting medical conditions can be found in Table 19-6.[17]

It may be easier to identify/manage adverse medication effects and easier to manipulate to alter the timing of the menstrual cycle in patients taking monophasic COCs.[3,4] Continuous COCs either eliminate or reduce the number of menstrual cycles per year, leading to less premenstrual symptoms and dysmenorrhea. Commercially available continuous COCs or monophasic 28-day OCs can be cycled by skipping the 7-day placebo phase. With continued use of extended-cycle or continuous COCs for 1 year, no significant changes in adverse effects have been noted. However, long-term studies have not been performed to assess the risk of cancer, VTE, or changes in fertility. Extended-cycle regimens provide a shortened pill-free interval, from the traditional 7 days to 2 to 4 days. These various extended-cycle and continuous regimens may be beneficial for patients with symptoms such as dysmenorrhea, severe premenstrual syndrome, or menstrual migraines.

Managing Combined Oral Contraceptive Adverse Medication Effects

⑥Adverse medication effects occurring with early COC use (eg, nausea, bloating, breakthrough bleeding) may improve spontaneously by the third cycle after adjusting to the altered hormone levels.[3,4,10,17] Patients should be counseled to continue their COC for 2 to 3 months before changing products unless a serious adverse effect is present. Despite the 2- to 3-month adjustment period, a large majority of individuals who discontinue COCs do so because of the adverse medication effects. Therefore, patient education and early reevaluation within 3 to 6 months are necessary to identify and manage adverse effects, and to improve adherence. The most common adverse effect is irregular bleeding. Individuals on extended-cycle regimens should be counseled to expect this during the first 6 months. For those experiencing bleeding irregularities beyond the recommended time frame, the estrogen or progestin content may need to be adjusted.[4,10,17] Early breakthrough bleeding is typically due to insufficient estrogen and late breakthrough bleeding is due to insufficient progestin. Nausea may occur due to the estrogenic effects of these hormonal contraceptives. Skin breakouts occur more often in products with higher androgenic effects. Serious adverse effects that may occur with the use of CHCs are listed in Table 19-4, and common adverse medication effects along with recommended monitoring are reviewed in Table 19-5.[3,4,10] Patients should be instructed to consult with their provider immediately and likely should discontinue CHCs if they experience serious warning signs, described as ACHES.[3,4]

TABLE 19-4

Symptoms of a Serious or Potentially Serious Nature Associated with Combined Hormonal Contraception

Symptom	Possible Cause
SERIOUS: Stop immediately	
Loss of vision, proptosis, diplopia, papilledema	Retinal artery thrombosis
Unilateral numbness, weakness, or tingling	Hemorrhagic or thrombotic stroke
Severe pains in chest, left arm, or neck	Myocardial infarction
Hemoptysis	Pulmonary embolism
Severe pains, tenderness or swelling, warmth or palpable cord in legs	Thrombophlebitis or thrombosis
Slurring of speech	Hemorrhagic or thrombotic stroke
Hepatic mass or tenderness	Liver neoplasm
POTENTIALLY SERIOUS: May continue with caution while being evaluated	
• Absence of menses • Spotting or breakthrough bleeding • Breast mass, pain, or swelling • Right upper-quadrant pain • Mid-epigastric pain • Migraine headache • Severe nonvascular headache • Galactorrhea • Jaundice, pruritus • Depression, sleepiness • Uterine size increase	• Cervical endometrial or vaginal cancer • Cholecystitis, cholelithiasis, or liver neoplasm • Pituitary adenoma • Cholestatic jaundice • B6 deficiency • Leiomyomata, adenomyosis

Data from References [3,4].

TABLE 19-5

Medication Monitoring Table for Hormonal Contraception

Medication (or Medication Class)	Adverse Medication Reactions	Monitoring Parameter	Comments
Combined hormonal contraception	• Nausea/vomiting • Breast tenderness • Weight gain • Acne, oily skin • Depression, fatigue • Breakthrough bleeding/spotting • Application site reaction (transdermal) • Vaginal irritation (vaginal ring)	• Patient symptoms • Weight • Visual inspection • Depression screening • Menstrual symptoms • Visual inspection • Patient symptoms	• Typically improves after two to three cycles; consider changing to lower estrogenic. • Consider changing to lower androgenic. • Data are limited and conflicting. • Consider changing to higher estrogenic.
Depo-medroxyprogesterone acetate	• Menstrual irregularities[a] • Weight gain • Acne • Hirsutism • Depression • Decreased bone density	• Menstrual symptoms • Weight • Visual inspection • Depression screening • bone mineral density (BMD)	• Typically improves after 6 months. • Data are limited and conflicting. • Do not routinely screen with dual-energy X-ray absorptiometry (DXA).
Levonorgestrel IUD	• Menstrual irregularities[a] • Insertion-related complications • Expulsion • Pelvic inflammatory disease (PID)	• Menstrual symptoms • Cramping, pain, spotting, dyspareunia, missing strings • Lower abdominal pain, unusual vaginal discharge, fever	• Typically spotting, amenorrhea • Prophylactic nonsteroidal anti-inflammatory drugs (NSAIDs) or local anesthetic may reduce occurrence. • IUD strings should be checked regularly to ensure IUD properly placed. • Risk of developing is rare, but counseling on STI/STD prevention is important.
Copper IUD	See levonorgestrel IUD above	See levonorgestrel IUD above	Menstrual irregularities are typically heavier menses with copper IUD.
Progestin-only implant	• Menstrual irregularities[a] • Insertion-site reactions	• Menstrual symptoms • Pain, bruising, skin irritation, erythema, pus, fever	Typically well tolerated and resolved without treatment; infection is rare.

[a] Suggested management of irregular bleeding may include use of NSAIDs for 5 to 7 days; hormonal treatment (if medically eligible) with COC or estrogen therapy for 10 to 20 days of treatment.

Data from References 3,10.

Managing Combined Oral Contraceptive Medication Interactions

④⑥⑦The effectiveness of a COC is sometimes limited by medication interactions that interfere with GI absorption, increase intestinal motility due to altered gut bacteriologic flora, and alteration of the metabolism, excretion, or binding of the COC.[2] The lower the dose of hormone in the COC, the greater the risk that a medication interaction will compromise effectiveness. Individuals should be instructed to use an additional method of contraception if there is a possible medication interaction altering COC effectiveness.[4] Although less well documented, these recommendations generally apply to patients receiving transdermal and vaginal CHC products.

Rifampin is the one with a true documented COC pharmacokinetic interactions.[3,10] Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but individual case reports have shown a reduction in EE levels when OCs are taken with tetracyclines and penicillin derivatives, possibly due to the inhibition of enterohepatic recirculation. Individuals receiving concomitant rifampin (or derivatives) and OCs should be counseled on the possibility for decreased efficacy and to use an additional nonhormonal contraception while on the combination and for at least 7 days after the rifampin therapy has been discontinued. Some OC manufacturers recommend to use a backup method for 28 days after the use of any enzyme inducer such as rifampin.[10,17,18] It may be prudent to inform patients of the slight risk of decreased effectiveness with other antimicrobials as well; however, this is not necessarily supported with strong evidence. If a patient is going to be receiving an interacting medication for more than 2 months, switch to depot medroxyprogesterone acetate (DMPA) or an IUD to avoid the interaction and eliminate the need for long-term additional nonhormonal contraception.

⑦Individuals receiving certain anticonvulsants for a seizure disorder should be offered another form of contraception such as DMPA or LARC methods rather than OCs (see Table 19-6).[17] Some anticonvulsants (mainly phenobarbital, carbamazepine, phenytoin) induce the metabolism of estrogen and progestin, inducing breakthrough bleeding and potentially reducing contraceptive efficacy. In addition, some antiseizure medications are known as teratogens. Use of COCs with lamotrigine may decrease the effectiveness of lamotrigine and increase the possibility of worsening the seizure disorder.

TABLE 19-6

U.S. Medical Eligibility Criteria for Contraceptive Use: Classifications for Combined Hormonal Contraceptives

Category 4: Unacceptable health risk (method not to be used) • Breastfeeding or non-breastfeeding <21 days postpartum • Current breast cancer • Severe (decompensated) cirrhosis • Current DVT/PE • History/higher risk of DVT/PE (not on anticoagulant therapy) • History/higher risk of DVT/PE (established on anticoagulant therapy for 3 months or greater) • Thrombogenic mutations • Major surgery with prolonged immobilization • Migraines with aura, any age • Systolic BP ≥160 mm Hg or diastolic ≥100 mm Hg • Hypertension with vascular disease • Current and history of ischemic heart disease • Benign hepatocellular adenoma or malignant liver tumor • Peripartum cardiomyopathy, moderately or severely impaired cardiac function; normal or mildly impaired cardiac function <6 months • Smoking ≥15 cigarettes per day and age ≥35 • Complicated solid organ transplantation	• Diabetes mellitus (type 1 or type 2), nonvascular disease • Gallbladder disease; symptomatic and treated by cholecystectomy or asymptomatic • Migraines without aura • History of pregnancy-related cholestasis • History of high BP during pregnancy • Benign liver tumors; focal nodular hyperplasia • Obesity • Breastfeeding 30-42 days without other VTE risk factors • Breastfeeding 42 days or more postpartum • Non-breastfeeding 21-42 days postpartum without risk factors for VTE • Rheumatoid arthritis on or off immunosuppressive therapy • Smoking and <35 years old • Uncomplicated sold organ transplantation • Stable SLE without antiphospholipid antibodies

- History of cerebrovascular accident
- SLE; positive or unknown antiphospholipid antibodies
- Complicated valvular heart disease

Category 3: Theoretical or proven risks usually outweigh the advantages

- Breastfeeding 21-30 days postpartum with or without risk factors for VTE
- Breastfeeding 30-42 days postpartum with risk factors for VTE
- Non-breastfeeding 21-42 days postpartum with other risk factors for VTE
- Past breast cancer and no evidence of disease for 5 years
- History of DVT/PE (not on anticoagulant therapy or established on anticoagulant therapy for at least 3 months), but lower risk for recurrent DVT/PE
- Current gallbladder disease, symptomatic and medically treated
- History of bariatric surgery; malabsorptive procedures (*COCs only, vaginal ring/transdermal patch category 1)*
- History of cholestasis, past COC-related
- Hypertension; systolic BP 140-159 mm Hg or diastolic 90-99 mm Hg
- Adequately controlled hypertension
- Peripartum cardiomyopathy, normal or mildly impaired cardiac function ≥6 months
- Smoking <15 cigarettes per day and age ≥35
- Use of fosamprenavir
- Use of certain antiseizure medications (phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine, and lamotrigine)
- Use of rifampicin or rifabutin therapy
- Diabetes with vascular disease or >20 years duration (*possibly category 4 depending upon severity*)
- Multiple risk factors for arterial cardiovascular disease (older age, smoking, diabetes, low HDL, high LDL, or high triglycerides and hypertension) (*possibly category 4 depending on category and severity*)
- Acute flare of viral hepatitis (*possibly category 4 depending on severity [initiation]*)
- Multiple sclerosis with prolonged immobility
- Current or history of superficial venous thrombosis

Category 2: Advantages generally outweigh theoretical or proven risks

- Age ≥40 (in the absence of other comorbid conditions that increase CVD risk)
- Sickle cell disease
- Undiagnosed breast mass
- Cervical cancer and awaiting treatment; cervical intraepithelial neoplasia
- Family history (first-degree relatives) of DVT/PE
- Major surgery without prolonged immobilization
- Unexplained vaginal bleeding before evaluation
- Uncomplicated valvular heart disease
- Use of antiretrovirals other than fosamprenavir (*category 1 or 2 depending on agent*)
- Use of St. John's wort
- Inflammatory bowel disease (*possibly category 3 for those with increased risk of VTE*)
- Acute flare of viral hepatitis occurring during use of product (*continuation, category 3 or 4 for initiation of product)*

Category 1: No restriction (method can be used)

- Thalassemia, iron deficiency anemia
- Mild compensated cirrhosis
- Benign ovarian tumors
- Benign breast disease or family history of cancer
- Family history of cancer
- Schistosomiasis
- Cystic fibrosis
- Cervical ectropion
- Viral hepatitis (carrier/chronic)
- Minor surgery without immobilization
- Depression
- Gestational diabetes mellitus
- Endometrial cancer/hyperplasia, endometriosis
- Epilepsy
- Gestational trophoblastic disease
- Nonmigrainous headaches
- History of bariatric surgery; restrictive procedures
- History of pelvic surgery
- HIV infected or high risk
- Malaria
- Multiple sclerosis without prolonged immobility
- Ovarian cancer
- Past ectopic pregnancy
- Parity, parous, or nulliparous
- PID
- Postabortion
- Non-breastfeeding >42 days postpartum
- Severe dysmenorrhea
- STIs
- Varicose veins
- Vaginal bleeding—irregular pattern without heavy bleeding or heavy, prolonged bleeding
- Thyroid disorders
- Tuberculosis
- Uterine fibroids
- Use of SSRIs
- Use of broad-spectrum antibiotics, antifungals,

	and antiparasitics

CVD, cardiovascular disease; DVT, deep vein thrombosis; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PE, pulmonary embolism; PID, pelvic inflammatory disease; SSRI, selective serotonin reuptake inhibitors.

Data from Reference [17].

Other medications that may affect COCs include HIV antiretrovirals such as protease inhibitors which, depending on the HIV medication, may decrease COC effectiveness or the COC may possibly alter the levels of protease inhibitor.[17] In addition, monitoring of potassium levels may be needed in individuals who take medications that increase potassium with drospirenone-containing COCs. Drospirenone is a derivative of spironolactone, a potassium-sparing diuretic, that also has anti-mineralocorticoid activity. Caution may be warranted in patients with a history of hyperkalemia or in patients taking concomitant medications that increase potassium levels or in high-risk patients taking strong inhibitors of CYP3A4.[18] Patients should also be counseled that an OTC herbal product, St. John's wort, may also possibly decrease OC effectiveness. Because there are several possible medication interactions that could affect the levels of COCs, assess all patient medications for possible interactions with COCs.[17]

Patient Instructions with Combined Oral Contraceptives

⑨Many individuals who take OCs are not educated properly on the appropriate use of these medications. They should be given the package insert that accompanies all products and instructed to read it, as well as supplementing this information with verbal education describing the mechanism of the medication, common and serious adverse medication effects (ie, ACHES symptoms), and their management. Although several transient self-limiting adverse medication effects often occur, the patient should be aware of the danger signals that require immediate medical attention (see Table 19-4). The benefits and risks should be discussed, including the fact that OCs provide no physical barrier to the transmission of STIs/STDs, including HIV. Detailed instructions on when to start taking the OC should be provided. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve adherence.

Missed Doses of Combined Oral Contraceptives

⑧Specific instructions should be given regarding what to do if a tablet is missed.[10] For individuals who routinely have difficulty with adhering to daily dosing, counseling regarding other options such as the vaginal ring, transdermal patch, DMPA, implants, or IUDs should be provided. If warranted, suggesting EC may also be necessary.

For COCs, if one tablet is missed or late then it should be taken as soon as remembered, and the rest of the tablets should be continued as prescribed (for most this that means two tablets are taken on the same day). Typically no additional nonhormonal contraception methods are warranted. If two or more consecutive tablets are missed then take one missed tablet as soon as remembered and discard the other missed tablets. Continue taking the OC tablets as scheduled which means two tablets may need to be taken on the same day (ie, one of the missed tablets and one of the regularly scheduled tablets). If tablets were missed in the last week of hormonal tablets, finish the remaining active tablets (tablets with hormone) and then omit the hormone-free interval (skip taking the placebo tablets) and start a new pack of tablets. For both of these scenarios, counsel patients to use additional nonhormonal contraception until active hormone tablets have been taken for seven consecutive days. For all scenarios when two or more consecutive tablets are missed, consider counseling on EC use if warranted.

Vomiting and Severe Diarrhea While on Combined Oral Contraceptives

⑥⑨Efficacy of COCs may be decreased when vomiting or severe diarrhea occurs, and recommendations for dosing in this situation have been developed.[10] These recommendations are based on theoretical concerns and are identical to missed tablet instructions. If vomiting or diarrhea occurs for less than 48 hours, then no redosing of COCs is warranted. If vomiting or diarrhea persists greater than 48 hours then continue taking tablets. If this scenario occurs during the last week of the hormonal tablets, then finish the tablets, skip the hormone-free tablets, and begin a new pack. Patients should be instructed to use additional nonhormonal contraception until hormonal tablets have been taken for seven consecutive days after the vomiting or diarrhea subsides and counsel patients on use of EC if warranted.

Transdermal Contraceptives

③④⑤There are two CHCs available as transdermal patches (Xulane, originally marketed as Ortho Evra, and Twirla). Xulane is a 14-cm^2 square transdermal patch that delivers 35 mcg of EE and 150 mcg of norelgestromin, the active metabolite of norgestimate.[3,4,19] Twirla is a 28 cm^2 circular patch that provides 30 cmg of EE and 120 mcg of levonorgestrel daily.[5] The EE/norelgestromin patch is as effective as COCs in patients weighing less than 90 kg. Of the 15 pregnancies reported in the clinical trials, five were among individuals weighing more than 90 kg; therefore, this product is not recommended as a first-line option for these patients.[3,4,19,20] Similar to the EE/norelgestromin patch, the EE/levonorgestrel patch is recommended for individuals with a BMI of less than 30 kg/m^2, but may also have reduced effectiveness with BMIs ranging from 25 to 30 kg/m^2.[5,19,20] Typical-use failure rates for EE/norelgestromin and EE/levonorgestrel patches are 7% and 3%, respectively (Table 19-1).[3,5]

Managing Transdermal Patch Contraceptive Adverse Medication Effects and Medication Interactions

⑥⑦Some patients experience application-site reactions, but other adverse medication effects are similar to those experienced with COCs (eg, breast discomfort, headache, breakthrough bleeding, and nausea).[4] A warning from the EE/norelgestromin manufacturer states that individuals using the patch are exposed to approximately 60% more estrogen than from a typical COC containing 35 mcg of EE, which may lead to an increased thromboembolic risk. The labeling for these patches now contains a warning of this risk.[5,17] Medication interactions with the patches are similar to those of COCs. Please see Managing Combined Oral Contraceptive Medication Interactions.

Patient Instructions with Transdermal Patch Contraceptives

⑨The patch is designed to provide estrogen (EE) and progestin (norelgestromin or levonorgestrel) for 7 days. One patch should be worn at a time and applied to the abdomen, buttocks, upper torso, or upper arm. Start applying the patches at the beginning of the menstrual cycle. They should be changed weekly on the same day which is labeled the "Patch Change Day." Apply a new patch weekly for 3 weeks with the fourth week being patch-free for a 4-week cycle.[3,4,5,19]

Missed Doses of Transdermal Patch Contraceptives

⑧⑨If the patch detaches and is off less than 24 hours, the detached patch or a new patch can be reapplied, and no additional hormone contraception necessary. If application is delayed for more than 24 hours, start a new 4-week cycle by applying a new patch as soon as possible. An additional nonhormonal contraception should be utilized until the new patch has been worn for 7 consecutive days. This will be the new "Patch Change Day."[15,19] If the delayed application or detachment occurs in the third patch week, the hormone-free week should be omitted and a new patch should be applied immediately.[5,10,19]

If an individual forgets to change the patch at the end of the week, instructions on what to do vary based on where they are in the cycle.[5,19] If they forget to apply a new patch after the hormone-free week, they will need to use a backup method of nonhormonal contraception until they has worn a patch for 7 days. If they forget to apply a new patch in weeks 2 or 3 (left an active hormone patch on and forgot to replace it with a new one) and the delayed application is for only 1 or 2 days (up to 48 hours), a new patch should be applied immediately.[5,19] The next patch should be changed on the same "Patch Change Day," and no backup contraception is needed. If the delayed application of a new patch (old one is still on) is longer than 2 days (more than 48 hours), then they will need to start a new 4-week cycle of patches and use a backup nonhormonal method of contraception until a new patch has been placed for 7 days.[5,19] If the patient forgets to remove the patch for the hormone-free week, they should remove it as soon as they remember and start the next cycle of patches on the regular "Patch Change Day" (day after day 28 of the cycle). No backup contraceptive method is required in this situation. There should not be more than 7 days where a patch is not worn. If this occurs, the individual must use a backup nonhormonal contraceptive method until a new patch has been applied for 7 days.[5,19] Users have greater adherence with the patch than with an COC, but whether this results in reduced pregnancy rates remains to be seen.[3] The benefits of adherence must be weighed against the risk of increased estrogen exposure and possibility of VTE.

Vaginal Rings

③④⑤There are two marketed vaginal contraceptive rings (NuvaRing and Annovera). NuvaRing is a 54-mm flexible ring, 4 mm in thickness which when vaginally inserted releases approximately 15 mcg/day of EE and 120 mcg/day of etonogestrel.[20] It is formulated to be used for 3 weeks and then discarded.

Annovera is 56 mm in diameter and 8.4 mm in cross-sectional diameter vaginally inserted ring which releases 13 mcg of EE and 150 mcg of segesterone acetate.[6] It is formulated to be used for 3 weeks at a time, but is not discarded. It is used again for a total of 13 cycles.

The vaginal ring is as effective as COCs.

Patient Instructions with Vaginal Ring Contraceptives

⑨On the first cycle of use, the ring should be inserted on or before the fifth day of the menstrual cycle, remain in place for 3 weeks, then removed for 1 week to allow for withdrawal bleeding. The ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new COC pack or transdermal patch on the same day of the week.

In contrast to diaphragms and cervical caps, precise placement is not an issue because the hormones are absorbed anywhere in the vagina. Individuals should be in a comfortable position, and compress the ring between the thumb and index finger to push it into the vagina. There is no danger of inserting the ring too far because the cervix will prevent it from traveling up the genital tract. Removal of the ring is performed in a similar manner, pulling it out. The NuvaRing should be discarded into the foil patch (the ring should not be flushed down the toilet).[21] The Annovera ring should be removed, washed with warm water, and placed in its original container for later use. After one ring-free week, the Annovera ring can be vaginally inserted again and can be used for a total 13 cycles. Annovera does not require refrigeration, however, NuvaRing may require it if not being used promptly. Individuals should be discouraged from douching, but other vaginal products, including antifungal creams and spermicides, can be used.[3,6,21]

Missed Doses of Vaginal Ring Contraceptives

⑧⑨If the NuvaRing has been displaced for less than 3 hours, or less than 2 hours for Annovera, a new ring should be inserted as soon as possible and kept in until the scheduled removal day, with no additional nonhormonal contraception necessary.[6,21] If there is a delay of 3 or more hours, for NuvaRing or 2 or more hours for Annovera, a new ring (for NuvaRing) or current ring (Annovera) should be inserted immediately and either additional nonhormonal contraception should be utilized, or intercourse should be avoided until the ring has been in place for seven consecutive days. If the delayed reinsertion occurs during the third week of ring use, a new ring (for NuvaRing) or current ring (for Annovera) can be reinserted right away to start the next 21-day cycle. There may be some spotting or vaginal bleeding.

If a person forgets to remove the ring after the third week, and there has been prolonged use of the ring for up to one extra week (not more than 4 weeks in place for NuvaRing), they will still be protected and no backup protection will be necessary. Though, the individual should take into account the number of extra weeks the Annovera ring was inserted vaginally and subtract those weeks from the total 13 cycles for use. The ring should be removed for the ring-free week, and a new ring can be inserted after the ring-free week. If NuvaRing has been left in place longer than 4 weeks, the ring should be removed. The individual should then check for possible pregnancy. Once pregnancy has been ruled out, a new cycle of the vaginal ring with 7 days of a nonhormonal contraceptive method may be started.[6,21] With Annovera, a ring-free week should occur and then the regular 3-week ring cycle should be restarted.

Managing Vaginal Ring Contraceptive Adverse Medication Effects and Medication Interactions

⑥⑦Adverse medication effects, precautions, and contraindications for use of the vaginal ring are similar to those for all CHCs. Specific medication interactions with Annovera have been reported that include 1-day or the 3-day oil-based miconazole suppository use increasing exposure up to 67% for EE and 32% for segesterone acetate. These medications and oil-based vaginal suppositories should be avoided with Annovera. Water-based products may be used. Unlike NuvaRing, tampon use with Annovera should be avoided until further studies are completed. The most common reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms.[6,21] Cycle control with the vaginal ring appears to be equal or better than with COCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use. Patient acceptability of the delivery system has been studied, and the majority of patients do not complain of discomfort in general or during intercourse.[4,6,21] A potential concern is the possibility of increased VTE.[6,21]

Considerations with Combined Hormonal Contraceptive Use

②③④⑤When selecting a CHC, clinicians are challenged by weighing the benefits and risks associated with the many formulations available. The clinician must determine if the form of contraception is appropriate based upon the patient's lifestyle and potential adherence. A complete medical examination and papanicolaou (Pap) smear are not necessary before a CHC is prescribed. A medical history and BP measurement should be obtained before prescribing a CHC, along with a discussion of the benefits, risks, and adverse effects with each patient.[3,10,17] For example, OCs are associated with noncontraceptive benefits, including relief from menstruation-related problems (eg, decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss), improvement in menstrual regularity, alleviating acne and premenstrual dysphoric disorder, and decreased iron deficiency anemia.[3] Individuals who take COCs have a reduced risk of ovarian and endometrial cancer, which a 50% reduction after 5 years or more. This protection may persist for more than 10 years post-use.[3] COCs may also reduce the risk of ovarian cysts, ectopic pregnancy, pelvic inflammatory disease (PID), endometriosis, uterine fibroids, and benign breast disease. The CHC transdermal patches and vaginal rings are combined hormonal options that may be more convenient than taking a tablet each day.

③④⑥⑨Adverse effects may hinder adherence and therefore efficacy, so they should be discussed prior to initiating a hormonal contraceptive agent.[10,17] Excessive or deficient amounts of estrogen and progestin are related to the most common adverse effects.[3,10] An important concern regarding the use of CHCs is the lack of protection against STI/STDs. Because of their high efficacy in preventing pregnancy, patients may choose not to use condoms. In addition to public health awareness, clinicians must encourage patients to use condoms for prevention of STI/STDs. The health risks associated with pregnancy, the specific health risks associated with CHCs, and the noncontraceptive benefits of CHCs should be factored into risk-to-benefit considerations. To help provide guidance on absolute and relative contraindications to CHC use, the CDC developed a graded list of precautions for clinicians to consider when initiating CHCs (Table 19-6).[10,17]

Individuals Older than 35 Years

Use of a CHC in individuals older than 35 is controversial. Older individuals, especially those in their 40s, retain a level of fertility even in the perimenopausal state and can use hormonal contraception to prevent pregnancy. Formulations with lower doses of estrogen (less than 30 mcg) have increased the use of CHCs in these individuals. In addition to the benefit of pregnancy prevention, they may improve or decrease the chance of developing perimenopausal and menopausal symptoms and increase bone mineral density (BMD). However, the benefits of using CHCs must be weighed against the risks in individuals older than 35. The increased risk of VTE should be considered especially in perimenopausal individuals older than 40. Older data suggest an increased risk of myocardial infarction (MI) is present in older individuals using CHCs, although many of who in these studies were current smokers and used older formulations containing higher doses (greater than 50 mcg) of estrogen. There is no increased risk of cardiovascular disease when low-dose formulations of CHCs are used in healthy, nonobese individuals. Other concerns include the increased risk of ischemic stroke in those with migraines and the increased risk of breast cancer in older individuals.[4,17]

The risks and benefits of using CHCs in individuals greater than 35 must be considered on an individual basis. The use of CHCs (with less than 50 mcg of estrogen) may be considered in healthy nonsmoking individuals. CHCs should not be recommended in individuals older than 35 years with migraine (with aura), uncontrolled hypertension, smoking, or diabetes with vascular disease.[4,17]

Smoking

COCs with 50 mcg EE or more were associated with MI in individuals who smoked cigarettes.[3,4] The United States case-control studies have found that both nonsmoking and smoking individuals taking OCs with less than 50 mcg EE did not have an increased risk of MI or stroke, regardless of age. However, these studies included few patients older than 35 years who were smokers. European studies, with a higher population of older smoking individuals, demonstrated an increased risk of MI in this population. Therefore, practitioners should prescribe CHC with caution, if at all, to those older than 35 years who smoke. Smoking 15 or more cigarettes per day by those in this age group is a contraindication to CHCs, and the risks generally outweigh the benefits of CHCs in those who smoke fewer than 15 cigarettes per day.[4,17] Progestin-only or nonhormonal contraceptive methods should be considered for individuals in this group.

Hypertension

CHCs can cause small increases (ie, 6-8 mm Hg) in BP, regardless of estrogen dosage.[4,17] This is presented in both normotensive and mildly hypertensive individuals when given an OC with 30 mcg EE. OCs have been associated with an increased risk of MI and stroke. Use of low-dose CHC is acceptable in those younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in BP occurs, CHC discontinuation usually restores BP to pretreatment values within 3 to 6 months.[4] Systolic BP ≥160 mm Hg or diastolic BP ≥100 mm Hg is considered a contraindication to the use of CHCs. Hypertensive individuals who have a systolic BP of 140 to 159 or diastolic BP of 90 to 99 mm Hg should also avoid CHCs as the risks generally outweigh the benefits. Risks versus benefits should be considered for those who have additional cardiovascular risk factors along with hypertension. Individuals with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC-containing drospirenone, which has anti-aldosterone properties.[4,7,18]

Dyslipidemia

Generally, synthetic progestins may adversely affect lipid metabolism by decreasing high-density lipoprotein (HDL) and increasing low-density lipoprotein (LDL).[4,17] Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. They may also moderately increase triglycerides. Today, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol, although historically this was not felt to be true. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not atherosclerosis. CHCs use is generally acceptable in individuals with dyslipidemia as the single cardiovascular risk factor. However, careful consideration should be taken in persons with dyslipidemia along with other cardiovascular risk factors and in many cases alternative methods of contraception may be recommended.

Diabetes

Any effect of CHCs on carbohydrate metabolism is thought to be due to the progestin component.[4,17] However, most products used today contain low doses of progestins and do not significantly alter insulin, glucose, or glucagon release or daily insulin requirements. CHCs do not appear to alter the hemoglobin A_{1C} values or accelerate the development of microvascular complications in individuals with diabetes. Therefore, nonsmoking patients younger than 35 years with diabetes but no associated vascular disease can safely use CHCs. Diabetic individuals with vascular disease (eg, nephropathy, retinopathy, neuropathy, or other vascular disease) or diabetes of more than 20 years duration should not use CHCs.[4,17]

Migraine Headaches

Individuals with migraine headaches may experience a decreased or an increased frequency of migraine headaches when using CHCs.[4,17,22] A higher risk of stroke is seen in patients experiencing migraine with aura compared to those with simple migraine. The risk of stroke in individuals with migraines has been elevated twofold to threefold. However, given the low absolute risk of stroke in those less than 35 years of age, CHCs in healthy, nonsmoking individuals with migraine headaches without aura may still be considered.[17] Likewise, individuals with nonmigrainous headaches may also use CHCs without restriction. However, individuals of any age who have migraine with aura should not use CHC,[1] and those who develop migraines with aura while receiving CHC should discontinue use and consider a progestin-only option.[17] Individuals developing migraines without aura while receiving a CHCs should have their headaches evaluated to determine severity, evaluate for signs of an aura, and to discuss the risk versus benefit of CHC use.[17]

Breast Cancer

Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high-dose OCs) were collected to assess the relationship between COCs and breast cancer.[3,4] Overall, investigators noted a small increase in the relative risk of having breast cancer diagnosed while COCs are taken and for up to 10 years following discontinuance. There is no increased excess risk of diagnosis 10 years or more after COCs are discontinued. A 2010 analysis of data from the Nurses' Health Study also found that individuals who used OCs had a slight increase in breast cancer risk.[23] In 2017, a large prospective Danish study reported breast cancer risks associated with more recent formulations of COCs.[24] Overall, those who were using or had recently discontinued using hormonal contraception had a modest (20%) increase in the relative risk of breast cancer compared with individuals who had never used hormonal contraception. The risk increased the longer the hormones were used and in individuals over the age of 40. If hormones are discontinued, the breast cancer risk returns to the same levels seen for persons who never used them, although it may take longer for those who had taken for more than 5 to 10 years. For healthy young individuals, the benefits of hormonal contraception in preventing unwanted pregnancies and associated other benefits outweigh any risks. For those over the age of 40 or those who have an elevated risk of breast cancer because of family history or other factors, alternatives may be considered. The choice to use CHCs should not be affected by the presence of benign breast disease or a family history of breast cancer with either mutation. In individuals identified with BRCA1 or BRCA2 mutations, increased risk of breast cancer with COCs has been controversial. The results of two large, case-controlled studies have found conflicting results. Until additional data refutes or affirms these studies, it is important to understand these risks and assure they are discussed with patients as even a small increase in risk may be clinically important.[25,26] Patients with current or past history of breast cancer should not use CHCs.[3,4,17]

Thromboembolism

Estrogens increase hepatic production of factor VII, factor X, and fibrinogen in the coagulation cascade, therefore increasing thromboembolic event risk (eg, deep vein thrombosis and pulmonary embolism). These risks are increased in individuals who have underlying hypercoagulable states (eg, deficiencies in antithrombin III, protein C, and protein S; factor V Leiden mutations, prothrombin G2010 A mutations) or who have acquired conditions (eg, obesity, pregnancy, immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities.[3,4,17] The incidence of thromboembolism and mortality is increased threefold in current OC users compared to nonusers. However, this risk is still less than the risk of VTE incurred during pregnancy. COCs containing new progestins such as third-generation progestins (eg, desogestrel and norgestimate) and a fourth-generation progestin (eg, drospirenone) have been associated with a slightly higher risk of thromboembolism.[3,4] Although the mechanisms for this increased risk is unclear, this increased risk may be due to: (a) a greater effect on the procoagulant, anticoagulant, and fibrinolytic pathways than earlier generation progestins; (b) an increased resistance to the anticoagulant effect of activated protein C; (c) increased levels of sex hormone-binding globulin; and (d) antiandrogenic effects of drospirenone make the CHC more estrogenic.[2,3,27,28] A continuous, higher exposure to estrogen seen with the transdermal patch or vaginal ring is the reason for an increased thromboembolic risk with these agents as well.[27] An advisory committee to the FDA decided to change the product labeling of the transdermal patch as well as products containing drospirenone to include additional information about the increased risk of thromboembolism.[18,19] In addition, the vaginal ring also has an additional precaution in the product labeling.[21] Therefore, for individuals at an increased risk of thromboembolism (eg, older than 35 years, obesity, smoking, personal or family history of venous thrombosis, prolonged immobilization), it would be prudent to first consider low-dose oral estrogen contraceptives containing older progestins, progestin-only contraceptive methods, or barrier methods. A recent systematic review of progestin-only contraceptives did not suggest an overall significant increase in venous or arterial events.[29] Limited evidence suggests slight increases in thromboembolism in those using these for therapeutic indications or in those with other thromboembolic risk factors. Any slight increase in risk likely translates to a small increase in absolute numbers of thrombotic events at the population level.

Weighing the risks versus benefits of using CHCs containing third- and fourth-generation progestins, transdermal patch, and vaginal ring to determine their place in therapy is controversial. The risk of VTE with CHC use is 3 to 12 per 10,000 person-years, compared with 1 to 5 per 10,000 person-years in non-CHC users and nonpregnant biologically female individuals.[3] The risk increases to about 10 per 10,000 person-years with drospirenone-containing COCs.[30] Risk of VTE is also higher with the transdermal patch and possibly with the vaginal ring.[30] A continuous, higher exposure to estrogen seen with these formulations may be the cause of this increased risk. Regardless of contraceptive product, the risk is still lower than the risk of thromboembolism during pregnancy (5-20 per 10,000 person-years).[27,31]

Obesity

The prevalence of obesity continues to rise each year among all age groups including patients of childbearing age. Individuals with increased body weight have increased basal metabolic rates and induction of hepatic enzymes, leading to increased hormonal clearance and decreased serum concentrations of hormonal contraceptives. In addition, patients who are obese have more adipose tissue, increasing hormonal sequestration, and decreased free hormone serum concentrations resulting in lower efficacy.[3,4] There is an additional two to four pregnancies per 100 person-years of use in overweight or obese users.[20,32] Regardless of body weight, IUDs, implants, and DMPA have low failure rates, and progestin-only contraceptives are considered safe in obese indiiduals.[17,20] In addition, the advantages of using an estrogen-containing contraceptive method (pill, patch, ring) generally outweigh the risks.[10,17] DMPA is associated with more weight gain than other methods.[3] With regard to EC, the copper IUD is the most reliable method in obese individuals. Oral EC products may be less effective and the effectiveness of levonorgestrel, in particular, is diminished.[33]

Obese individuals are also at risk of VTE, although studies evaluating the incidence of thromboembolism in obese persons taking hormonal contraceptives have produced conflicting results. With low-dose estrogen containing products, the incidence increases from 5 to 10 cases in nonusers to 15 to 30 cases in users per 10,000 person-years. At baseline, obesity doubles the risk of thromboembolism compared to someone with a normal BMI. Progestin-only hormonal contraception may be more appropriate for obese individuals over the age of 35 years, although the CDC considers the benefits of estrogen-containing contraceptives to outweigh the risks as well.[17,20] Patients should be counseled on any risks and consider alternative contraceptive methods on an individual basis.[20] The risk of thromboembolism during pregnancy and in the peripartum period is significantly greater than the risk with any hormonal contraceptive agent.

Postpartum Use of CHCs

In the postpartum phase, there is concern about use of CHCs due to hypercoagulability risks and the effects on lactation. In the first 21 days postpartum (when the risk of thrombosis is higher), estrogen-containing hormonal contraceptives should be avoided (see Table 19-6).[17] If contraception is required during this period, progestin-only contraceptive methods may be acceptable alternatives. Individuals breastfeeding muss avoid CHCs for the first 42 days postpartum if they have risk factors for VTE and for 30 days without risk factors. In those individuals who are not breastfeeding, CHCs should be avoided for up to 42 days postpartum in those with risk factors for VTE.[17] After 42 days postpartum, there is no restriction to the use of CHCs.

Systemic Lupus Erythematosus

Contraception is important in biologically female individuals with systemic lupus erythematosus (SLE) because the risks associated with pregnancy are high in this population. CHCs exacerbated the symptoms of SLE,[4] postulating that estrogen may cause cutaneous lupus to progress to systemic lupus by promoting B-cell hyper-responsiveness and inducing or increasing autoimmunity.[4] OCs with less than 50 mcg ethinyl estradiol do not increase the risk of flare in individuals with stable SLE without antiphospholipid/anticardiolipin antibodies. Therefore, CHCs should be avoided in patients with SLE and antiphospholipid antibodies or vascular complications as the risks outweigh the benefits of progestin-only contraceptive use in patient population. The copper IUD may be the best option in this situation.[17] For patients with SLE without antiphospholipid antibodies or vascular complications, progestin-only contraceptives or the copper IUD may be an alternative to CHCs; however, those with SLE and severe thrombocytopenia should avoid the copper IUD and DMPA injection.[17]

Discontinuing Combined Hormonal Contraceptives and Return of Fertility

There is no evidence that CHC, transdermal patches, or vaginal ring use decreases subsequent fertility.[3] Return to fertility with CHC use is usually within a few months.[3] However, delayed ovulation is more common in individuals with a history of irregular menses. If amenorrhea does continue beyond 6 months, patients should be counseled to see a physician for further fertility workup.[3,4] Individuals were counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menses and ovulation. However, infants conceived in the first month after discontinuation of an OC had no greater chance of miscarriage or being born with a birth defect than those born in the general population.

Progestin-Only Contraceptives

③④⑤There are a few hormonal contraceptives that contain only progestin. Formulations include oral tablets, injections, a subdermal implant, and IUDs. Sustained progestin exposure blocks the LH surge, thus inhibiting ovulation. Should ovulation occur, progestins reduce ovum motility in the fallopian tubes. Even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. Individuals who may benefit from progestin-only contraceptives are those who are breastfeeding, those who are intolerant to estrogens (ie, have a history of estrogen-related headache, breast tenderness, or nausea), or those with concomitant medical conditions or contraindications in which estrogen is not recommended (see Table 19-6). This method of contraception does not provide any protection from STIs/STDs.[3,4]

Oral Progestin-Only Contraceptives and Administration

⑧⑨There are two progestin-only oral products available, norethindrone and drospirenone. Norethindrone tablets are also known as “minipills” and have similar effectiveness to COCs with a perfect-use failure rate of 0.3% and typical-use failure of 7% (Table 19-1).[3] The norethindrone 35-mg product consists of 28 days of active hormone per cycle, which must be taken every day of the menstrual cycle at approximately the same time to maintain contraceptive efficacy. As with other OCs, initiating norethindrone tablets may be done any time during the cycle. If taken within the first 5 days of menstrual bleeding, a backup contraceptive method is not required. Starting any other time in the cycle requires an additional contraceptive method for 2 days.[10] If a norethindrone-only OC is taken more than 3 hours late, patients should use a backup method of contraception for 48 hours.[3]

Drospirenone 4-mg tablets known as the product Slynd contain 24 days of active hormone and 4 days placebo. Drospirenone-only tablets have a typical-use failure rate of 4%.[7] Slynd can be started on day 1 of menses with no additional backup method. If started later in the cycle, a backup contraceptive method is required.[7] There is more flexibility in dose administration with drospirenone compared with norethindrone, a missed dose is considered more than 24 hours after the scheduled administration time. The individual can take the missed tablet as soon as possible and continue with the pill pack as no backup contraception is needed. If two or more active tablets are missed, the individual should take the last missed tablet as soon as possible and continue taking one tablet daily as instructed while using an additional contraceptive method for 7 days.[7]

Oral Progestin-Only Contraceptives Adverse Effects, and Considerations

③⑥⑦Progestin-only pills may not block ovulation, as nearly 40% of patients continue to ovulate normally, so the risk of ectopic pregnancy is higher with their use than with other hormonal contraceptives. Common progestin adverse medication effects may include: irregular menses, acne, headache, nausea, or libido changes. Drospirenone products may have less acne adverse medication effects, but may need monitoring for thromboembolism, hyperkalemia, and bone loss.[7]

Medication interactions are also a consideration for oral progestin-only tablets. In particular, norethindrone formulations are metabolized via the liver through the cytochrome P450 system. Medications that induce the P450 system like phenytoin, carbamazepine, oxcarbazepine, primidone, topiramate, protease inhibitors, and St. John’s wort, as examples may affect oral progestin metabolism.[17] With the exception of rifampin, broad spectrum antibiotics do not affect levels of oral progestins.[17] Considerations for drospirenone-only tablets also include medications that may increase potassium levels, such as ACE inhibitors, potassium-sparing diuretics, and high-dose ibuprofen. The concurrent use of these medications with drospirenone should be avoided due to the potential risk of hyperkalemia.

Similar to estrogen containing contraceptives, oral progestin-only contraceptives should be avoided in individuals with a history of breast cancer, unexplained bleeding, and SLE with antiphospholipids. Caution may be needed in patients with a history of current VTE, complicated diabetes, heart or hepatic disease.[17] Starting oral progestin contraceptives postpartum or while breastfeeding may be used though follow-up may be required per the CDC recommendations.[17]

Progestin Injections

Steroid hormones provide longer-term contraception when injected into the skin. In addition, injectable progestins are beneficial for individuals with adherence issues, as they have lower failure rates than CHC methods (see Table 19-1).[3,6,17]

Depo-Provera (DMPA) is similar in structure to naturally occurring progesterone and is administered every 3 months either by deep intramuscular injection in the gluteal or deltoid muscle or subcutaneously in the abdomen or thigh within 5 days of onset of menstrual bleeding.[34,35] With perfect use, the efficacy of DMPA is more than 99%; however, with typical use, 3% of individuals experience unintended pregnancy.[3] The primary mechanism of action is suppression of ovulation. Depo-Provera is available as a 150 mg/mL injection vial or prefilled syringe for IM injection, and Depo-SubQ Provera 104 mg is available as a prefilled syringe.[34,35] The subcutaneous formulation is also FDA approved for use in treating endometriosis. Administration of both formulations of DMPA requires a medical office visit; however, studies of patient self-administration of subcutaneous DMPA have demonstrated positive results.[36,37]

Progestin Injection Administration

⑤⑧⑨Depo-Provera may be administered at any time as long as it is reasonably certain that the patient is not pregnant.[1,34,35] If it is administered between days 1 and 7 of the menstrual cycle in individuals who have not previously used hormonal contraception, then no backup method is needed.[10] If it is administered at any other time of the menstrual cycle, then an additional nonhormonal contraceptive is needed as backup method for 7 days. Additional recommendations on initiating the implant when switching from other methods of contraception are included in the package insert.[34,35] Although these injections may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The patient must be confirmed to not be pregnant if there is a lapse of more than 13 weeks between injections for the intramuscular formulation or 14 or more weeks between injections for the subcutaneous formulation. However, CDC recommendations differ and state for either formulation, and pregnancy should be excluded in individuals with a lapse of 15 or more weeks.[10]

Progestin Injection Considerations

③④⑤⑥As with other contraceptive agents, concomitant conditions should be evaluated prior to use of DMPA. Although no adverse effects have been documented in infants exposed to DMPA through breast milk, DMPA must not be initiated until 6 weeks postpartum in breastfeeding patients.[34,35] However, the CDC cites a lack of evidence supporting this claim and classifies DMPA use during this time frame as a category 1 or 2 suggesting that the benefit may outweigh the theoretical risk.[17] Patients who are not breastfeeding but require contraception can receive DMPA immediately postpartum.[17] It is contraindicated in individuals with a current diagnosis of breast cancer due to potential hormonally sensitive tumors, and should be used with precaution in those with a past history of breast cancer, vascular, cardiovascular, or cerebrovascular disease, multiple risk factors for cardiovascular disease, and lupus. There is some concern that the impact of DMPA on lipids (potentially decreased HDL) and the hypoestrogenic pharmacologic effects may increase the risk of a vascular event. However, the risks with DMPA are much lower than with CHCs so risks and benefits should be weighed on an individual basis.[17] Patients with sickle cell disease are good candidates for DMPA, due to a reduction in sickle cell pain crises in those using DMPA.[17] In addition, patients with seizure disorders may experience fewer seizures when taking DMPA for contraception, and there is not a concern with antiseizure medications reducing the contraceptive efficacy of DMPA.[3,17] Because return of fertility may be delayed after discontinuation of DMPA, it should not be recommended to individuals desiring pregnancy in the near future. The median time to conception from the first omitted dose is 10 months and 68% of those are able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.[3,34,35]

Progestin Injection Adverse Effects

⑥Menstrual irregularities are the most frequent adverse effects of both formulations of DMPA and are most common in the first year of use. These irregularities include spotting, prolonged bleeding, and amenorrhea; counseling patients on these possibilities is important before initiation of the method.[10,17] Individuals who cannot tolerate prolonged bleeding may benefit from a short course of NSAIDs (for 5-7 days) during the bleeding, and in addition, a short course of estrogen (if no contraindications are present) for approximately 10 to 20 days.[4] The incidence of irregular bleeding decreases from 30% to 50% in the first 2 years to 10% thereafter, and after 12 months of therapy, 55% of patients report amenorrhea, with the incidence increasing to 68% after 2 years.[34,35]

Other adverse effects, including breast tenderness and depression, occur less commonly. Weight gain is a concern for many patients using DMPA, and the incidence and amount gained vary widely. It has been reported that weight gain averages 1 kg annually and may not resolve until 6 to 8 months after the last injections. In clinical trials 38% of patients reported a weight gain of great than 10 lbs (4.5 kg) at 24 months.[3,4,34,35] However, use of DMPA in obese patients should not be excluded. Appropriate consideration of multiple factors should be evaluated for obese patients and individualized decisions made. For all patients, weight and BMI should be monitored for patients receiving DMPA.[10,17]

DMPA has been associated with short-term bone loss in younger individuals of reproductive age. This potential side effect may be due to lower ovarian estrogen production that occurs when gonadotropin secretion is suppressed.[3,38] Because longitudinal studies demonstrated effects on BMD, the FDA issued a black box warning for DMPA in 2004.[34,35] It states that DMPA should be continued for more than 2 years, only if other contraceptive methods are inadequate. It also states that the loss of BMD seems to be greater with increasing duration of use and may not be completely reversible. However, the majority of clinicians view the effects of DMPA on BMD (which in the majority of cases is reversible) as a surrogate marker and there are no clear data that demonstrate the effects of DMPA on fracture risk.[38,39] The ACOG and CDC continue to recommend that for most patients the benefits of DMPA outweigh the risks even when used beyond 2 years of use.[10,36] It is not routinely recommended to use DMPA in individuals on long-term corticosteroids (eg, patients with rheumatoid arthritis) with a history or high risk of fractures.[17] While the ACOG does not recommend the routine screening of BMD in most patients, a discussion regarding the risks and benefits of this contraceptive option is recommended prior to initiation and with prolonged use.[38]

Subdermal Progestin Implants

③④⑤Nexplanon (similar to the original product Implanon marketed in the United States) is a single 4-cm-long implant, containing 68 mg of etonogestrel, which releases etonogestrel at a rate of 60 mcg daily for the first month, then decreases to an average of 30 mcg daily at the end of the 3 years of recommended use. The etonogestrel implant is placed under the skin of the upper arm using a preloaded inserter,[3,40] and clinicians must receive training from the manufacturer to properly insert or remove of the device. The primary mechanism of action is suppression of ovulation. When ovulation is not suppressed, etonogestrel still is effective as the progestin thickens the cervical mucus and produces an atrophic endometrium. With both perfect and typical use, the efficacy rate is over 99%.[3,40] However, in overweight and obese individuals weighing more than 130% of their ideal body weight, the efficacy is possibly decreased. However, it is noted that overweight individuals were excluded from studies, and recent small studies have not demonstrated any decreased effects.[40]

Progestin Implant Insertion

⑨The etonogestrel implant can be inserted at any time as long as it is reasonably certain the individual is not pregnant.[13,40] If the implant is inserted between days 1 and 5 of the menstrual cycle in those who have not previously used hormonal contraception then no backup method is needed.[13,40] If it is inserted at any other time of the menstrual cycle, then an additional nonhormonal contraceptive is needed as backup method for 7 days. Additional recommendations on initiating the implant when switching from other methods of contraception are included in the package insert.[40] After removal, fertility returns within 30 days.

Progestin Implant Adverse Effects

⑥The major adverse effect associated with Nexplanon is irregular menstrual bleeding, which led to discontinuation of the implant in 11% of patients in clinical trials.[40,41] Patients should be counseled about the risk of irregular bleeding patterns so that patients will not request early removal of Nexplanon. Some individuals (22%) became amenorrheic with continued use, but many continued to have prolonged bleeding and spotting (18% and 34%, respectively) and frequent bleeding (7%).[10,40] Those who cannot tolerate prolonged bleeding may benefit from a short course of NSAIDs (for 5-7 days) during the bleeding and from a short course of estrogen (if no contraindications are present) for approximately 10 to 20 days.[14] Insertion and removal complications are rare (less than 2%).[40] Nexplanon is radio opaque, making it easy to locate for removal by conducting an x-ray if needed.[13] Information from the manufacturer suggests using precaution when there is potential for medication interactions in the presence of potent CYP450 inducers (eg, rifampin, phenytoin, and carbamazepine).[40] This information conflicts with CDC recommendations which classify combining those medications with Nexplanon as a category 2, and suggest that the benefits may outweigh the theoretical risks. However, the CDC does still recommend use of additional nonhormonal contraception or switching to DMPA or an IUD as the preferred methods of managing these potential medication interactions.[17]

Intrauterine Devices

③④⑤Currently, five IUDs are available, four of them contain levonorgestrel (Mirena, Skyla, Liletta, and Kyleena), one contains copper (ParaGard T 380A, many times referred to as ParaGard). All of the mentioned IUDs are T-shaped and clinicians must receive training from the manufacturer to learn effective insertion or removal of the IUDs. These IUDs have several possible mechanisms of action, including inhibition of sperm migration, damaging ovum or disrupting transport, and possibly damaging the fertilized ovum.[3] Due to the presence of local progestin, the Mirena, Skyla, Liletta, and Kyleena IUDs have additional mechanisms of endometrial suppression and thickening cervical mucus. The most recent evidence regarding the mechanisms of action demonstrates that the contraceptive activity of IUDs occurs before implantation.[3,41] Efficacy rates with IUDs are greater than 99% with both perfect- and typical-use,[3,41] and should not be inserted in the presence of current pregnancy, current PID, current STI/STD, puerperal or postabortion sepsis, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of genital tract, uterine anomalies or fibroids distorting uterine cavity, allergy to an IUD component, or Wilson's disease (for copper IUD).[42,43] If an IUD is already in place and the patient contracts an STI/STD, the IUD in most cases can remain in place while the STI/STD is being treated.[3,17] The risk of PID among IUD users is low, and there are no long-term effects on fertility, and average time to return of fertility is similar to oral contracpetives.[41] The influence of medication interactions on the efficacy of IUDs is not a primary concern based on manufacturer and CDC recommendations.[42-46]

⑥ ⑨ ParaGard is a highly effective IUD that contains copper and can be left in place for 10 years.[3,42] A disadvantage of ParaGard is increased menstrual blood flow and dysmenorrhea, as the average monthly blood loss among users increased by 35%. Mirena, Skyla, Liletta, and Kyleena contain the progestin levonorgestrel and are approved for the prevention of pregnancy in the United States.[42-46] Mirena is also approved for up to five years of use for the treatment of heavy menstrual bleeding.[43] Liletta and Mirena can be used for up to 6 years and release 20 mcg of levonorgestrel daily, decreasing over time.[43,44] Kyleena can be used for up to 5 years and releases 17.5 mcg of levonorgestrel daily, decreasing over time.[46] Skyla can be used for up to 3 years and releases 14 mcg of levonorgestrel daily, decreasing over time.[45] For all of the levonorgestrel IUDs, the systemic absorption of the progestin is minimal and considerably less than with OCs. There are no direct comparisons of safety or efficacy; when used appropriately all are highly effective and well tolerated.

Intrauterine Device Insertion

⑨ IUDs can be inserted at any time as long as it is reasonably certain that the user is not pregnant.[10] If the IUD is inserted between days 1 and 7 of the menstrual cycle in those who have not previously used hormonal contraception, then no backup method is needed. If it is inserted at any other time of the menstrual cycle, then it is recommended to use an additional nonhormonal contraceptive backup method for 7 days. Additional recommendations on initiating an IUD when switching from other methods of contraception are included in the package inserts.

Concerns about pain and infection upon insertion of the IUD are common; however, for most patients, insertion-pain is minimal and is not prolonged. If needed, common OTC pain relievers such as NSAIDs or acetaminophen may be helpful. Premedicating with misoprostol or paracervical lidocaine blocks have been studied,[10] but based on the evidence, misoprostol is not recommended for most patients due to lack of efficacy. Paracervical lidocaine blocks may be recommended for pain reduction, but it is not a commonly accepted standard of care. Risk of infection upon IUD insertion is minimal, and it is not recommended to prophylactically treat with antibiotics.[10] Individuals with current PID or STI/STD should delay having their IUD inserted. In contrast, users with an IUD in place that develop PID or an STI/STD should treat the infection, but it is not typically recommended to remove the IUD. Users who have not been screened for STI/STDs according to CDC guidelines should be screened at the same time as insertion. If results come back positive, then the STI/STD can be treated at that time.[10]

Intrauterine Device Adverse Effects

⑥ The major adverse effect associated with IUDs is irregular menstrual bleeding. The levonorgestrel IUD produces its effects locally via suppression of the endometrium, causing a reduction in menstrual blood loss over time. In contrast to the copper IUD, menstrual flow in users of the levonorgestrel IUD is decreased, and development of amenorrhea has been observed in 20% of users in the first year and 60% in the fifth year. Mirena specifically has an additional indication for treatment of heavy menstrual bleeding (menorrhagia).[42] A disadvantage of the levonorgestrel IUD is increased spotting in the first 6 months of use; users should be counseled that the spotting will decline gradually over time.[3,42] Those who cannot tolerate prolonged bleeding may benefit from a short course of NSAIDs (for 5-7 days) during the bleeding. In addition, a short course of estrogen (if no contraindications are present) could be used for approximately 10 to 20 days.[10]

IUD use in nulliparious and adolescent individuals was considered a precaution. However, recent evidence, clinical experience, and expert opinion do not preclude use in these populations. Risks versus benefits should be considered, and the users must be counseled on the efficacy and potential adverse effects.[41,47] Strong consideration of an IUD is appropriate in this population due to high efficacy rates and low complication rates.[47] In addition, Skyla and Liletta included adolescent patients less than 18 years of age in clinical trials.[44,45]

Long-Acting Reversible Contraception

③ ⑤ Long-acting reversible contraception (LARC) refers to a category of hormonal and nonhormonal contraceptives that include IUDs and implants.

This type of contraception is highly efficacious in preventing pregnancy, but the effects are quickly reversible upon removal.[41] As LARC does not require effort or adherence by the patient once they are inserted, perfect-use and typical-use efficacy rates do not differ, and the efficacy rate is similar to that of surgical options such as tubal ligation (see Table 19-1).[3,41] When compared to other methods of hormonal contraception, especially OCs, LARC methods are not used as frequently in the United States; however, increased education campaigns are demonstrating effectiveness. The use of LARC has increased to 14% of all individuals biologically female between the ages of 15 to 44,[48] and all patients should be considered potential candidates for this method.[41,47] Due to the high efficacy rates and emerging evidence of LARC methods, increased use may decrease unintended pregnancy rates.[41]

Emergency Contraception

⑩EC is used to prevent unintended pregnancy after unprotected or inadequately protected sexual intercourse (eg, no contraception, condom breakage, contraceptive mishap, or nonadherence, sexual assault). Pregnancy occurs when the fertilized egg is implanted into the endometrial lining. After intercourse, implantation of the fertilized egg typically takes approximately 5 days.[49] Progestin-only and progesterone receptor modulator products are approved by the FDA and recommended as first-line EC options.[3,4,49] Insertion of ParaGard (copper IUD) or prescribing higher doses of COCs (Yuzpe method) are other options.

Currently, the progestin-only formulation containing levonorgestrel 1.5 mg tablet × 1 dose (currently marketed in a variety of products, including Aftera, EContra EZ, EContra One-Step, My Way, New Day, Opcicon One-Step, Plan B One Step, Preventeza, React and Take Action) is approved specifically for EC in the United States.[13,16] The primary mechanism of action of progestin-only EC is inhibiting or delaying ovulation.[49] The levonorgestrel-containing EC formulation is the regimen of choice due to availability, improved tolerability, and potentially increased efficacy rates. All formulations are now offered as one-dose options, to be given within 72 hours (3 days) of unprotected intercourse. However, the earlier the medication is given, the greater the efficacy and less chance of a pregnancy. Notably, This regimen may be effective for up to 5 days after unprotected intercourse; but consideration of ulipristal or the copper IUD may be a better option if a patient can get access in time.[49] Levonorgestrel-containing EC products are available without a prescription to patients of all ages in the United States.[49]

⑩Ulipristal acetate (ella One) was approved for use as an EC and is a selective progesterone receptor modulator with mixed progesterone agonist and antagonist properties.[49,50] Its mechanism of action depends on the timing of administration relative to the patient's menstrual cycle.[50,51] However, the primary mechanism of action appears to be delay of ovulation. Ulipristal acetate is available by prescription only as a single dose of 30 mg taken within 120 hours (5 days) after unprotected intercourse so that it maintains efficacy for the full 120-hour window.[49,50] Data also exist to support noninferiority of ulipristal acetate compared to levonorgestrel-containing EC.[52]

Ulipristal acetate is not recommended for use in breastfeeding patients. Ulipristal acetate affects progesterone receptors and may interfere with ongoing hormonal contraception. A reliable barrier method is recommended for intercourse that occurs in the same menstrual cycle with ulipristal acetate use, even if the patient is on a regular hormonal contraceptive. In addition, the individual should avoid using a hormonal contraceptive method or initiating a new hormonal contraceptive for at least 5 days after ulipristal acetate administration.[50] Taking hormonal contraception sooner may alter the effect of ulipristal acetate as well as may compromise the effect of the hormonal contraceptive.[50]

⑩Determining the exact effectiveness rate of EC is difficult; however, the range has been reported to be between 59% and 94%.[49] EC may prevent an average of 75% of expected pregnancies when taken appropriately. Individuals must have an advanced prescription on hand or access to an OTC formulation to maximize the effectiveness of EC.

Controversy exists regarding the potential for decreased efficacy of oral EC (both levonorgestrel and ulipristal) in overweight or obese individuals. No large-scale studies have been designed to fully resolve the controversy, and data from randomized trials have suggested an association with increased body weight and decreased efficacy of oral EC.[53,54] However, data demonstrate that there may be a decline in efficacy of levonorgestrel in females weighing greater than 75 kg. As oral EC is the most widely used EC method due to its accessibility, this issue is controversial. In 2016, the FDA announced that there was not enough evidence to change levonorgestrel labeling and encouraged further studies.[53] There is no effect of increased body weight on efficacy of a copper IUD.

⑥ Common adverse effects of EC include nausea, vomiting, and irregular bleeding.[49] Nausea and vomiting occur significantly less when progestin-only and progesterone receptor modulator EC is administered. Many patients will experience irregular bleeding regardless of which EC method is used, with the menstrual period usually occurring 1 week before or after the expected time. Routine screening prior to or after receiving progestin-only and progesterone receptor modulator EC is not recommended. If a pregnancy already exists, the oral EC will not disrupt or harm the embryo. In addition, there are no contraindications to the use of these methods of EC (for the Yuzpe and copper IUD methods clinicians must adhere to their contraindications and precautions). No current data regarding the safety of repeated-use EC are available, but current consensus suggests that the risks are low, and patients can receive multiple regimens if warranted, though use of a regular ongoing contraceptive should be encouraged. Appropriate counseling should be provided regarding timing of the dose, common adverse effects, and use of a regular contraceptive method (additional nonhormonal contraceptive methods should be used after EC for at least 7 days).

Pregnancy Termination

⑪ For various reasons, medications may be needed for pregnancy termination. There are a variety of protocols and considerations that will not be covered in depth within this chapter. Medications used in early pregnancy (≤70 days) termination supported by most national and international medical organizations include mifepristone and misoprostol typically used in combination or with misoprostol alone.

Mifepristone is a steroid that binds progesterone receptors and causes abortion by blocking progesterone, softening the cervix, increasing uterine contractility, and increasing prostaglandin sensitivity.[3,55] Progesterone is needed to maintain the corpus luteum during pregnancy. Softening of the cervix and increasing prostaglandins also affects the pregnancy by stimulating contractions. Mifepristone is usually administered orally.[3,56] Prescribing of mifepristone is restricted to a prescriber that has met the training and qualifications of the manufacturer, and it is only dispensed out of the prescriber's facility. Although it is only used short term for pregnancy termination, it requires monitoring for medication interactions as it is metabolized by the CYP450 3A4 system. Therefore, caution should be taken when administered with strong inhibitors or inducers of that system.[57]

Boxed warnings for mifepristone include infection and bleeding.[57] Bacterial infections and sepsis may occur without findings upon pelvic examination after the abortion or without signs of infections such as bacteremia and fever. Excessive bleeding may occur and could be a sign of incomplete abortion or other complications and needs prompt medical attention.[57] Prescribers need to inform patients of these risks prior to use and also educate patients on what to do if they feel they experience these events by discussing a patient agreement created by the manufacturer. When used as an abortifacient, mifepristone is contraindicated in patients with bleeding disorders or on anticoagulants.[57]

Misoprostol is a prostaglandin E1 analog, currently marketed as a protective agent in patients at risk for gastric ulcers that also causes softening of the cervix and stimulates uterine contractions. Off-label uses include abortion, labor induction, preventing and treating postpartum hemorrhage, cervical ripening for medical procedures, and treatment of early pregnancy loss.[55] Adverse medication effects of misoprostol may include stomach upset, diarrhea, headache, dizziness, chills, and fever.[3,55,56] There are a variety of dosage forms available, including oral, vaginal, buccal, and sublingual. The oral form is not recommended because of decreased efficacy, as the other formulations have better adsorption. In addition, the vaginal route may cause less gastrointestinal adverse medication effects.[55]

Abortion regimens include mifepristone–misoprostol (most common), or misoprostol used alone. The mifepristone–misoprostol regimen approved for use by the FDA includes mifepristone 200 mg orally on day 1 and then misoprostol 800 mcg administered buccally 24 to 48 hours after the mifepristone dose.[3,4,55] The efficacy of this regimen has been reported as 98% in pregnancies up to 49 days.[55] Efficacy is higher if the regimen is used earlier in the pregnancy. The mifepristone–misoprostol regimen, compared to misoprostol alone, works faster and is more effective in later gestational ages.[3,55]

In all cases, further assessment by the treating provider is required in the days that follow medication administration to ensure complete abortion and to assess for any complications. Abdominal cramps and bleeding are common after medical abortion.[3,55] An individual should be counseled that they will likely have heavy menstrual bleeding, but it is important for them to recognize if there is too much bleeding.[55] Those experiencing bleeding that soaks two maxi pads per hour for 2 consecutive hours should contact their healthcare provider promptly.[55] Acetaminophen or NSAIDs such as ibuprofen may be used to help relieve pain and cramping.[3,55] Use of NSAIDs inhibit new prostaglandins but will not affect the use of misoprostol in pregnancy termination.

EVALUATION OF THERAPEUTIC OUTCOMES

⑨Selecting a contraceptive method should involve the patient and clinician using a shared decision-making model. Contraceptive pharmacotherapy should be personalized for each patient, taking into account desired outcomes from a contraceptive and noncontraceptive perspective. Factors to consider include effectiveness, presence of coexisting medical conditions or medications, safety, adverse effects, cost, return to fertility time, and patient preference of the contraceptive method (eg, long-acting, short-acting, hormonal, oral, nonoral, barrier). Patients should receive both verbal and written instructions on the chosen method of contraception. In addition, access to timely contraception is important. In addition, some states have (or are in the process of obtaining) expanded scope of practice to include provision of hormonal contraception by a pharmacist.[57,58] Follow-up appointments can increase adherence and provide opportunities to address other health maintenance issues. The contraceptive outcome of pregnancy prevention can be assessed when needed by obtaining a serum or urine pregnancy test.

Monitoring of the Pharmaceutical Care Plan

③④⑤⑧Contraceptive users should receive an annual preventative medicine exam that may include a cytologic screening (if appropriate) and pelvic and breast examination. Consultation should provide routine health maintenance screening and to assess for clinical problems or adverse effects related to contraception (see Tables 19-4, 19-5, and 19-6). These annual screenings do not have to occur prior to prescribing hormonal contraception.

Annual BP monitoring is recommended for all users of CHC. When a patient with a history of glucose intolerance or diabetes mellitus begins or discontinues the use of hormonal contraception, glucose levels must be monitored. Monitoring for the presence of adverse effects related to hormonal content or the presence of coexisting medical conditions is recommended for individuals using CHCs. Those using the etonogestrel implant should be monitored annually for menstrual cycle disturbances, local inflammation, or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Patients using DMPA should be asked at 3-month follow-up visits about weight gain, menstrual cycle disturbances, and fractures. Those using IUDs should be asked at 1- to 3-month follow-up visits about IUD placement (checking for IUD strings to assure the IUD is still in the proper position), changes in menstrual bleeding patterns, and symptoms and protection against STI/STDs. Clinicians should check for proper IUD positioning and symptoms of upper genital tract infection.

Finally, clinicians should monitor, and when indicated, screen for HIV and STIs/STDs. All individuals should receive counseling about healthy sexual practices including the use of condoms to prevent the transmission of STIs/STDs when necessary.

CONCLUSION

A variety of contraceptive methods are available. Selection of a contraceptive method depends on many factors. Patient preference, method effectiveness, medical history, contraceptive adverse medication effects, desire for a return to fertility, and available access to products all play a role in choosing the best contraception method for a patient. Clinicians play a critical role in helping patients carefully select an appropriate contraceptive method, monitoring adverse medication effects, and providing education on optimal use, effectiveness, and STI/STD prevention that can help reduce STI/STDs and unintended pregnancies.

ABBREVIATIONS

ACHES	abdominal pain, chest pain, headaches, eye problems, and severe leg pain
ACOG	American College of Obstetricians and Gynecologists
BMD	bone mineral density
BMI	body mass index
CDC	Centers for Disease Control and Prevention

CHC	combined hormonal contraceptive
COC	combined oral contraceptive
DMPA	depot medroxyprogesterone acetate
DXA	dual-energy x-ray absorptiometry
EC	emergency contraception
EE	ethinyl estradiol
FDA	Food and Drug Administration
FSH	follicle-stimulating hormone
GnRH	gonadotropin-releasing hormone
HDL	high-density lipoprotein
HIV	human immunodeficiency virus
IUD	intrauterine device
LARC	long-acting reversible contraception
LDL	low-density lipoprotein
LH	luteinizing hormone
MI	myocardial infarction
NSAID	nonsteroidal anti-inflammatory drug
OC	oral contraceptive
OTC	over-the-counter
Pap	papanicolaou (smear)
PMDD	premenstrual dysphoric disorder
SHBG-TBG	sex hormone (testosterone)-binding globulin
SLE	systemic lupus erythematosus
STI/STD	sexually transmitted infection/disease
TSS	toxic shock syndrome
VTE	venous thromboembolism

SELF-ASSESSMENT QUESTIONS

1. A 36-year-old individual who had difficultly adhering to medication schedules is seeking contraception. PMH: mitral valve prolapse. Current medications: Metoprolol Succinate Extended-Release 25 mg every day, multi-vitamin every day. Social history: smoker, occasional drinking. Family history: noncontributory. What would be the most appropriate product for this patient?

A. Combined oral contraceptive

B. Progestin-only oral contraceptive

C. Injectable depot medroxyprogesterone acetate.

D. Vaginal ring contraceptive

2. A 32-year-old patient comes to the pharmacy to pick up their prescription for an OC containing norgestimate 0.25 mg/ethinyl estradiol 35 mcg. This patient complains of significant nausea and headaches since starting her oral contraceptive 5 months ago. What is the most appropriate recommendation?

A. Call the physician to change the prescription to another OC with less estrogen.

B. Call the physician to change the prescription to another OC with less progestin.

C. Buy a home pregnancy test to rule out pregnancy.

D. Wait for another 1 to 2 months to see if symptoms improve.

3. A 36-year-old individual is considering starting drospirenone-only contraceptive tablets. Their medical history includes hypertension which is controlled by hydrochlorothiazide and ramipril and GERD for which famotidine is used as needed. Which of the following should be considered for the patient?

A. There are no issues to consider and discuss.

B. Drospirenone is contraindicated for use in patients with hypertension.

C. There may be a risk of hyperkalemia while using drospirenone and ramipril.

D. Famotidine may decrease the effectiveness of drospirenone.

4. An 18-year-old patient with a seizure disorder seeks contraception today. They are taking phenytoin and have a BMI of 32 kg/m^2. Which of the following contraceptive methods would be most appropriate?

A. Combined oral contraceptive

B. Intrauterine device

C. Transdermal contraceptive

D. Progestin-only pill

5. A 23-year-old patient comes to the pharmacy frantically asking for advice. It is the first week of their pill pack and their partner's condom broke last night during sexual intercourse. The patient states that they are currently taking a low-dose COC but missed the last two days of pills. The patient's BMI is 23 kg/m^2. What is best to recommend?

A. Take all missed pills today and resume normal dosing for remainder of the month. Backup protection is not needed.

B. Make an appointment with their physician to discuss the use of ulipristal.

C. Take the most recent missed pill as soon as possible and then resume normal dosing for the remainder of the month. No backup protection is needed.

D. Buy and use an OTC levonorgestrel-containing emergency contraception at the pharmacy.

6. A 28-year-old individual has been given a prescription for rifampin x 7 days. You notice that they also take the oral contraceptive, EE 35 mg/norgestimate 0.25 mg, for contraception. What is the most appropriate counseling point today?

A. They should change their contraceptive to a vaginal ring or transdermal patch.

B. They should add a barrier method to their current regimen while taking the antibiotic and for at least 7 days after and possibly up to 28 days after rifampin therapy.

C. They should ask their physician for a different antibiotic.

D. They should be switched to a high-dose estrogen OC to overcome the loss of estrogen effectiveness caused by the antibiotic.

7. Once discontinued, which of the following contraceptives is considered to have the longest return to fertility time?

A. Combined oral contraceptives

B. Progestin-only injection

C. Transdermal contraceptive patch

D. Progestin-only oral contraceptives

8. The World Health Organization and CDC Medical Eligibility Criteria for Contraceptive Use list which of the following as category 4 (a condition which represents an unacceptable health risk if the contraceptive method is used)?

A. Uterine fibroids

B. Cluster headaches

C. Hypertension with vascular disease

D. Obesity age over 30 years

9. LR is a 27-year-old patient who started on a low-dose COC containing 20 mcg of ethinyl estradiol 2 months ago and is currently nursing. They went out of town for the weekend and missed one dose of her medication yesterday. It is the second week of their pill pack and is now asking for your opinion on how they should handle the situation. What would be the most appropriate response?

A. Take the missed active tablet as soon as possible plus your regularly scheduled tablet for today (2 tablets total today) and then continue taking tablets daily, 1 each day as prescribed. No additional contraceptive protection is recommended.

B. Recommend an OTC levonorgestrel-containing emergency contraceptive.

C. Discard the current pack, allow bleeding to occur, and then restart a new pack, taking 1 tablet each day. Use condoms or abstain from sex until the new pill pack has been taken for 7 days in a row.

D. An OTC levonorgestrel-containing emergency contraceptive should be recommended, but because they is nursing, they cannot use it.

10. Your patient is a 39-year-old patient with a history of migraines with aura. They are a non-smoker and have two children with no immediate plans to get pregnant. This patient is obese (weighs 115 kg) and does not want to gain any more weight. What contraceptive method would be the best option?

A. Levonorgestrel IUD

B. Injectable depot medroxyprogesterone acetate.

C. Combined oral contraceptive

D. Vaginal ring contraceptive

11. Which of the following nonhormonal contraceptive methods do not require a prescription or an office visit to a clinician?

A. Cervical cap

B. Copper IUD

C. Diaphragm

D. Internal condom

12. Which of the following medications may be commonly used in pregnancy termination regimens?

A. Depot medroxyprogesterone acetate

B. Ethinyl estradiol

C. Mifepristone

D. Drospirenone

13. Use of the vaginal contraceptive ring would be most appropriate in which of the following situations?

A. 30-year-old patient with hypothyroidism

B. 38-year-old patient who smokes one pack per day

C. 36-year-old patient having migraines with aura

D. 28-year-old breastfeeding patient 18 days postpartum

14. AT is a 26-year-old patient with a history significant for depression and dysmenorrhea. They are currently using a transdermal contraceptive patch that fell off 5 days ago. Due to traveling, they were not able to place a new patch. They had unprotected sexual intercourse 4 days ago. What is the most appropriate recommendation?

A. Buy OTC levonorgestrel-containing emergency contraception at the pharmacy and counsel this patient to not restart their contraceptive transdermal patch for at least 5 days after taking the EC and use an alternate nonhormonal contraceptive in the meantime.

B. Buy a home pregnancy test.

C. Inform this patient that there is no EC option for this particular situation.

D. Call their clinician with a recommendation for a verbal order for ulipristal emergency contraception and counsel the patient to not restart their contraceptive transdermal patch for at least 5 days after taking the EC. They will need an alternate nonhormonal contraceptive in the meantime.

15. A 25-year-old single, nulliparous patient who is a nonsmoker with no significant medical history wants an easy method of contraceptive that they do not have to remember, is highly effective, and quickly reversible. What would you recommend?

A. Combined oral contraceptive

B. Progestin implant

C. Injectable depot medroxyprogesterone acetate

D. Progestin-only oral contraceptive

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Depot medroxyprogesterone acetate is the most appropriate recommendation. Combined hormonal contraceptives are contraindicated due to age and smoking history, so nonhormonal or progestin-only contraceptives are the remaining options. Progestin-only pills would not be appropriate for this patient due to a history of nonadherence. Refer to section on progestin-only pills and progestin injection.

2. **A.** Changing the OC to a product with less estrogen is the most appropriate recommendation. Nausea and vomiting is generally due to estrogen side effects. The patient is currently on a product with 35 mcg of ethinyl estradiol. Products with lower estrogen content are available and generally side effects become less over the first 3 months of use. As they has been using her product for 5 months, it would be appropriate to switch to another at this time. Refer to section on OCs and adverse effects.

3. **C.** Drospirenone is a derivative of the potassium sparing diuretic, spironolactone, and has some aldosterone blocking activity. It may increase potassium levels and may interact with ACE inhibitors such as ramipril increasing the risk of hyperkalemia. Famotidine does not affect drospirenone effectiveness and drospirenone may be used in patients with hypertension. Refer to the Progestin-Only Pills section.

4. **B.** The IUD would be the most appropriate recommendation, as it will not interact with the phenytoin, which is an enzyme inducer (see Table 19-6). agents will be affected and although less likely, vaginal and transdermal products may be affected as well.

5. **D.** In this particular situation, it would be important to counsel on starting EC sooner rather than later (ie, do not wait to make physician appointment). The patient is in her first week of taking hormones along with missing two tablets that puts her at risk for unintended pregnancy. For missed doses, if two or more consecutive tablets are missed then one missed tablet must be taken as soon as remembered and discard the remaining missed tablets. Continue taking the OC tablets as scheduled. Counsel to use additional nonhormonal contraception (such as condoms) until tablets have been taken for seven consecutive days. Consider use of EC based upon situation if unprotected intercourse occurred and in this case, the patient did have unprotected intercourse making EC the best option. Refer to EC section.

6. **B.** There has been clinical significance of an interaction with the antibiotic rifampin. It is therefore prudent to use a backup method throughout any antibiotic use and for at least 7 days after and possibly up to 28 days after rifampin therapy. The CDC does rate this a category 3 for use (Table 19-6). Do not increase the dose of estrogen in the OC, change contraceptive products, or change antibiotics when there is a short course of treatment and the patient is doing well otherwise.

7. **B.** The progestin-only injection, depot medroxyprogesterone, is considered to have the longest return to fertility reported to be as high as 12 months. OCs (combined and progestin-only) and transdermal contraceptives have a quicker return to fertility time. Refer to progestin-only injection and OC sections.

8. **C.** Hypertension with vascular involvement is the only category 4 diagnosis listed (see Table 19-6).

9. **A.** If one tablet is missed or late then the tablet must be taken as soon as remembered and the rest of the tablets must be taken as prescribed (for most patients that means two tablets taken on the same day). Typically, no additional nonhormonal contraception methods are warranted. Currently nursing does not affect any of the recommendations. Refer to the COC missed doses and EC section.

10. **A.** Since the patient has a history of migraines with aura, it would be recommended to avoid products with estrogen (Table 19-6) and best to use progestin-only or nonhormonal products. The progestin injectable form tends to cause more weight gain. Therefore, the IUD would be the most appropriate recommendation.

11. **D.** The internal condom is the correct choice since it is available OTC. All the other nonhormonal contraceptives listed (cervical cap, copper IUD, and diaphragm) do require a prescription and/or an office-visit with a clinician. See Table 19-2 and the "Nonpharmacologic Therapy" section.

12. **C.** Mifepristone is commonly used with other agents such as misoprostol for pregnancy termination regimens. Depot medroxyprogesterone acetate, ethinyl estradiol and drospirenone may be contained in various hormonal contraceptives and are not used for pregnancy termination. Refer to Pregnancy Termination section.

13. **A.** Hypothyroidism is not a contraindication for use of CHCs that include the contraceptive vaginal ring (Table 19-6). Smoking more than 15 cigarettes per day, along with being older than 35 years of age, is a contraindication to the use of contraceptives that contain estrogen. Migraines with aura and being less than 30 to 42 days postpartum are also contraindications to use of estrogen contraceptives due to increased risk of stroke and blood clots, respectively. In addition, if patients are having trouble with milk production, estrogen-containing contraceptives may decrease milk supply and are not recommended for those breastfeeding.

14. **D.** The ideal scenario would be to obtain a prescription for ulipristal acetate as it is labeled for use in patients who have had unprotected intercourse within 120 hours (5 days). OTC levonorgestrel is labeled for use within 72 hours of having unprotected intercourse. Levonorgestrel has an effectiveness up to 120 hours after intercourse, but the best option in this scenario is to obtain a prescription for ulipristal acetate if possible. There is also no concern with restarting hormonal contraception after using a levonorgestrel EC product, however, patients should be counseled to wait 5 days before restarting their hormonal contraception after taking ulipristal as hormonal contraceptives may interfere with the effectiveness of ulipristal. Another method of contraception should be used in the interim. Refer to EC section.

15. **B.** A long-acting reversible contraceptive (LARC) fits the criteria requested by the patient that includes high effectiveness, easy to use, and quickly reversible. Other LARC options include IUDs. Refer to progestin implant and LARC sections.

Chapter 30: Hypertension

Eric J. MacLaughlin; Joseph J. Saseen

KEY CONCEPTS

KEY CONCEPTS

① The risk of cardiovascular (CV) morbidity and mortality is directly correlated with blood pressure (BP).

② Evidence definitively demonstrates that antihypertensive drug therapy substantially reduces the risks of CV events and death in patients with high BP.

③ Essential hypertension is usually an asymptomatic disease. A diagnosis cannot be made based on one elevated BP measurement. An elevated BP value from the average of two or more BP measurements, present during two or more clinical encounters, is required to establish a diagnosis of hypertension.

④ The overall goal of treating hypertension is to reduce associated morbidity and mortality from CV events. Antihypertensive drug therapy should be selected based on evidence demonstrating CV event reduction.

⑤ A goal BP of <130/80 mm Hg is appropriate for nearly all patients with hypertension.

⑥ The magnitude of BP elevation should be used to guide the number of antihypertensive agents to start when implementing drug therapy. Most patients with stage 1 hypertension should start on one medication as initial therapy. Most patients presenting with stage 2 hypertension should be started on two medications as initial therapy.

⑦ Lifestyle modifications should be prescribed to all patients, especially those with elevated BP and hypertension.

⑧ Angiotensin-converting enzyme inhibitors (ACEi), angiotensin II receptor blockers (ARBs), calcium channel blockers (CCBs), and thiazides are preferred first-line antihypertensive agents for most patients with hypertension. These first-line options are for patients with hypertension who do not have a compelling indication for a specific antihypertensive drug class.

⑨ For most patients with hypertension, a -blocker is not an appropriate first-line treatment. While β-blocker will reduce CV events in hypertension compared to no treatment, it will not reduce CV events as much as has been demonstrated with an ACEi, ARB, CCB, or thiazide.

⑩ Compelling indications are comorbid conditions where specific antihypertensive drug classes have been shown in clinical trials to reduce CV events in patients with these specific comorbidities.

⑪ Older patients are often at higher risk for adverse reactions related to antihypertensive medications. Antihypertensive drug therapy selection should be the same as in younger patients, but lower initial doses should be used to minimize the risk of side effects in older patients.

⑫ Patients are categorized as having resistant hypertension when they fail to achieve goal BP while adherent to a regimen that includes three antihypertensive agents (one of which includes a diuretic) at full doses, or when four or more antihypertensive agents are needed to treat hypertension regardless of goal BP achievement.

⑬ Alternative antihypertensive agents should only be used in combination with first-line antihypertensive agents to provide additional BP lowering because they do not have sufficient evidence demonstrating CV event reduction.

BEYOND THE BOOK

BEYOND THE BOOK

Clinical Interaction: Patient with Hypertension

Prepare for this activity by completing the following tasks:

- View the instructional video “How to Use Your Home Blood Pressure Monitor” at: https://www.youtube.com/watch?v=K9HU2F3TOaI.
- Read the iForumRx.org commentary and listen to the podcast episode “Ten Things Every Clinician Should Know About the 2017 Hypertension Guidelines” available at: https://iforumrx.org/commentary/ten-things-every-clinician-should-know-about-the-2017-hypertension-guidelines/

Complete the activity by doing the following:

- Identify a patient with hypertension that has been prescribed 2 or more antihypertensive agents.
- Measure a patient’s BP using the technique demonstrated in the video.
- Engage in a brief discussion with your patient and address the following topics related to hypertension:
    - How long has the patient had hypertension?
    - What strategies does the patient use to take their antihypertensive medications regularly?
    - What does the patient believe are the benefits of the current antihypertensive drug regimen?
    - What does the patient identify as some of the risks of their current antihypertensive drug regimen?
    - How well does the patient think the drug therapy regimen is working?
    - What is the patient’s goal BP?
    - Has the patient taken any other antihypertensive medications in the past and how did he/she respond to them?
    - What lifestyle modifications does the patient engage in to help control BP?
- At the end of this interview, write some brief notes about this patient encounter.

INTRODUCTION

Hypertension is a common disease that is defined as persistently elevated arterial blood pressure (BP). Although elevated BP was perceived to be “essential” for adequate perfusion of vital organs during the early and middle 1900s, it is one of the most significant risk factors for cardiovascular (CV) disease for decades. Therefore, increasing awareness and diagnosis of hypertension and improving BP control with appropriate treatment are considered critical public health initiatives to reduce CV morbidity and mortality.

The 2017 American College of Cardiology/American Heart Association (ACC/AHA) guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults is the evidence-based clinical guideline in the United States to manage hypertension.[1] The 2017 ACC/AHA guideline provides recommendations on the definition of high BP, the diagnosis, patient evaluation, treatment goals, and management in various patient populations and provides additional strategies to improve BP control. This chapter incorporates relevant components of the 2017 ACC/AHA high BP guideline and additional evidence from clinical trials and meta-analyses, focusing on the pharmacotherapy for hypertension.

Pooled data from 2011 to 2014 indicate that approximately 103.3 million Americans aged 20 years and above met the definition of hypertension according to the 2017 ACC/AHA guideline.[2] More than half (53.4%) of the US adults taking antihypertensive medications had a BP above treatment goal. Considering the health consequences associated with high BP, there remain many opportunities for clinicians to improve the care of patients with hypertension.

EPIDEMIOLOGY

The definition of hypertension changed with the 2017 ACC/AHA guideline from a BP of ≥140/90 to ≥130/80 mm Hg. Hence, the prevalence of hypertension has increased considerably. According to the ACC/AHA definition, almost half (46%) of American adults aged 20 years and older have hypertension.[2] Although the overall prevalence has increased, only 1.9% would require additional drug therapy as the majority of newly diagnosed patients would require nonpharmacologic treatment only.[2]

The overall incidence of hypertension is similar between men and women but varies depending on age. The prevalence of high BP is higher in men than women before the age of 65 and is similar between the ages 65 and 74. However, after the age of 74, more women have high BP than men.[1] Prevalence rates are highest in non-Hispanic Blacks (59% in men, 56% in women), followed by non-Hispanic Whites (47% in men, 41% in women), non-Hispanic Asians (45% in men, 36% in women), and Hispanics (45% in men, 42% in women).[1]

BP values increase with age, and hypertension (persistently elevated BP values) is prevalent in older patients. The lifetime risk of developing hypertension among those 55 years of age and older who are normotensive is higher than 90%.[1] Most patients have elevated BP before being diagnosed with hypertension, with most diagnoses occurring between the third and fifth decades of life.

ETIOLOGY

Hypertension usually results from unknown pathophysiologic etiology (*essential* or *primary hypertension*). While this form of hypertension cannot be cured, it can be controlled. A smaller percentage of patients have a specific cause of their hypertension (*secondary hypertension*). There are many potential secondary causes of hypertension. If identified, hypertension in these patients can be mitigated or potentially be cured.

Primary Hypertension

Over 90% of individuals with high BP have essential or primary hypertension.[1] Numerous potential mechanisms have been identified that contribute to the pathogenesis of essential hypertension, so identifying the exact underlying abnormality is not possible. Genetic factors may play a role in developing essential hypertension by affecting sodium balance or other BP regulating pathways.

Secondary Hypertension

Secondary hypertension, where either a comorbid disease or a drug (or other product) is responsible for elevating BP (see Table 30-1), is much less common than primary hypertension (up to 10%).[1] In most cases, renal dysfunction resulting from severe chronic kidney disease (CKD) or renovascular disease is the most common secondary cause. Certain drugs (or other products) can directly or indirectly increase BP. The most common agents are listed in Table 30-1. When a secondary cause is identified, removing the offending agent (when feasible) or treating/correcting the underlying comorbid condition should be the first step in management.[1]

TABLE 30-1

Secondary Causes of Hypertension*a*

Diseases

- Chronic kidney disease
- Cushing's syndrome
- Coarctation of the aorta
- Obstructive sleep apnea
- Parathyroid disease
- Pheochromocytoma
- Primary aldosteronism
- Renovascular disease
- Thyroid disease

Medications

- Amphetamines (eg, amphetamine, dexmethylphenidate, dextroamphetamine, lisdexamfetamine, methylphenidate, phendimetrazine, phentermine)
- Antivascular endothelin growth factor agents (bevacizumab, sorafenib, sunitinib)
- Corticosteroids (cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone, prednisone, triamcinolone)
- Calcineurin inhibitors (cyclosporine, tacrolimus)
- Decongestants (pseudoephedrine, ocular phenylephrine)
- Ergot alkaloids (ergonovine, dihydroergotamine, methysergide)
- Erythropoiesis-stimulating agents (erythropoietin, darbepoetin)
- Estrogen-containing oral contraceptives
- Nonsteroidal anti-inflammatory drugs—cyclooxygenase-2 selective (celecoxib) and nonselective (aspirin [at higher doses], choline magnesium trisalicylate, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, ketorolac, meclofenamate, mefenamic acid, meloxicam, nabumetone, naproxen, naproxen sodium, oxaprozin, piroxicam, salsalate, sulindac, tolmetin)
- Testosterone
- Others: desvenlafaxine, venlafaxine, bupropion

Special situations with medications

- β-Blocker or centrally acting α-agonists (when abruptly discontinued)
- β-Blocker without α-blocker first when treating pheochromocytoma
- Use of a monoamine oxidase inhibitor (isocarboxazid, phenelzine, tranylcypromine) with tyramine-containing foods or certain drugs

Street drugs and other products

- Cocaine and cocaine withdrawal
- Methamphetamine
- Ephedra alkaloids (eg, Ma huang), "herbal ecstasy," other analogs
- Anabolic steroids
- Ergot-containing herbal products
- St. John's wort

Excessive Consumption of Food Substances

- Sodium
- Ethanol
- Licorice

[a] Agents of most clinical importance.

PATHOPHYSIOLOGY

Multiple physiologic factors control BP, and abnormalities of these factors are potential contributing components in developing essential hypertension. These include malfunctions in either humoral (ie, the renin-angiotensin-aldosterone system [RAAS]) or vasodepressor mechanisms, abnormal neuronal mechanisms, defects in peripheral autoregulation, and disturbances in sodium, calcium, and natriuretic hormones. Many of these factors are cumulatively affected by the multifaceted RAAS, which ultimately regulates arterial BP. No one factor is probably solely responsible for essential hypertension.

Arterial BP

Arterial BP is the pressure in the arterial wall measured in millimeters of mercury (mm Hg). The two arterial BP values are *systolic BP* (SBP) and *diastolic BP* (DBP). SBP represents the peak pressure achieved during cardiac contraction. DBP is achieved after contraction when the cardiac chambers are filling and represents the nadir pressure. The absolute difference between SBP and DBP is called the pulse pressure and measures arterial wall tension. Mean arterial pressure (MAP) is the average pressure throughout the cardiac contraction cycle. It can be used clinically to represent overall arterial BP, especially in a hypertensive emergency. During a cardiac cycle, two-thirds of the time is spent in diastole and one-third in systole. Therefore, the MAP is calculated by using the following equation:

$$\text{MAP} = \left(\text{SBP} \times \tfrac{1}{3}\right) + \left(\text{DBP} \times \tfrac{2}{3}\right)$$

MAP=(SBP×13)+(DBP×23)

Arterial BP is hemodynamically generated by the interplay between blood flow and the resistance to blood flow. It is mathematically defined as the product of cardiac output (CO) and total peripheral resistance (TPR) according to the following equation:

$$\text{BP} = \text{CO} \times \text{TPR}$$

BP=CO×TPR

CO is the primary determinant of SBP, whereas TPR largely determines DBP. In turn, CO is a function of stroke volume, heart rate, and venous capacitance. Table 30-2 lists physiologic causes of increased CO and TPR and correlates them to potential mechanisms of pathogenesis.

TABLE 30-2

Potential Mechanisms of Pathogenesis

Blood pressure (BP) is the mathematical product of cardiac output and peripheral resistance. Elevated BP can result from increased cardiac output and/or increased total peripheral resistance.	
Increased cardiac output	Increased cardiac preload: • Increased fluid volume from excess sodium intake or renal sodium retention Venous constriction: • Excess stimulation of the renin–angiotensin–aldosterone system (RAAS) • Sympathetic nervous system overactivity
Increased peripheral resistance	Functional vascular constriction: • Excess stimulation of the RAAS • Sympathetic nervous system overactivity • Genetic alterations of cell membranes • Endothelial-derived factors Structural vascular hypertrophy: • Excess stimulation of the RAAS • Sympathetic nervous system overactivity • Genetic alterations of cell membranes • Endothelial-derived factors • Hyperinsulinemia

Under normal physiologic conditions, arterial BP fluctuates throughout the day following a circadian rhythm. BP decreases to its lowest values during sleep, followed by a sharp rise starting a few hours before awakening, with the highest values occurring midmorning. BP also increases acutely during physical activity or emotional stress.

Classification

The classification of BP in adults (aged 18 years and older) is based on the average of two or more properly measured BP values from two or more clinical encounters (Table 30-3).[1] According to the ACC/AHA, there are four BP categories: normal, elevated, stage 1 hypertension, and stage 2 hypertension. Elevated BP is not a disease category but is associated with increased adverse CV risks compared to patients with normal BP.[3] It identifies patients whose BP is likely to progress to hypertension in the future, and thus for whom lifestyle modifications should be enacted to attenuate this progression.

TABLE 30-3

Classification of Blood Pressure in Adults (Age ≥18 Years)[a]

Classification	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)
Normal	<120	and	<80
Elevated	120-129	and	<80
Stage 1 hypertension	130-139	or	80-89
Stage 2 hypertension	≥140	or	≥90

[a] Classification is determined based on the average of two or more properly measured seated BP values from two or more clinical encounters. Out-of-office measurements should be used to confirm the diagnosis. If systolic and diastolic BP values yield different classifications, the highest category is used for the purpose of determining a classification.

Hypertensive crises are clinical situations where patients have extreme BP elevations, typically >180/120 mm Hg. They are categorized as either *hypertensive emergency* or *hypertensive urgency*. Hypertensive emergencies are extreme BP elevations that are accompanied by acute or progressing end-organ damage. Hypertensive urgencies are extreme BP elevations without acute or progressing end-organ injury.

Cardiovascular Risk and Blood Pressure

① Epidemiologic data demonstrate a strong correlation between BP and CV morbidity and mortality.[4] Risk of hypertension-associated complications (eg, stroke, myocardial infarction [MI], angina, heart failure [HF], kidney failure, early death from CV causes) is directly correlated with BP. Starting at a BP of 115/75 mm Hg, the risk of CV disease doubles with every 20/10 mm Hg increase.[1] Therefore, patients with elevated BP have an increased risk of CV disease.

② Treating patients with hypertension with antihypertensive drug therapy reduces the risk of CV events. Evidence from large-scale placebo-controlled clinical trials has repeatedly shown that the increased risks of CV events and death associated with elevated BP are reduced substantially by antihypertensive drug therapy (see 9 section).[5–8]

SBP is a stronger predictor of CV disease than DBP in adults aged 50 years and older; it is the most important BP parameter for most patients.[1] Patients are considered to have *isolated systolic hypertension* when their SBP values are elevated (ie, ≥130 mm Hg) and DBP values are normal (ie, <80 mm Hg). Isolated systolic hypertension is believed to result from pathophysiologic changes in the arterial vasculature, consistent with aging, that result in decreased compliance of the arterial wall and portend an increased risk of CV morbidity and mortality. A higher than normal pulse pressure (SBP minus DBP) is believed to reflect the extent of atherosclerotic disease in older patients and is a measure of increased arterial stiffness. Higher pulse pressure values are directly correlated with the risk of CV mortality.

Humoral Mechanisms

Several humoral abnormalities involving the RAAS, natriuretic hormone, and hyperinsulinemia may be involved in developing essential hypertension.

The Renin–Angiotensin–Aldosterone System

The RAAS is a complex endogenous system that is involved with most regulatory components of arterial BP. Activation and regulation are primarily governed by the kidney (see Fig. 30-1). The RAAS regulates sodium, potassium, and blood volume. Therefore, this system significantly influences the vascular tone and sympathetic nervous system activity and is the most influential contributor to the homeostatic regulation of BP.

FIGURE 30-1

Diagram representing the renin–angiotensin–aldosterone system. The interrelationship between the kidney, angiotensin II, and regulation of blood pressure is depicted. Renin secretion from the juxtaglomerular cells in the afferent arterioles is regulated by three major factors that trigger the conversion of angiotensinogen to angiotensin 1. The primary sites of action for major antihypertensive agents are included: ① ACE inhibitor; ② angiotensin II receptor blocker; ③ β-blocker; ④ calcium channel blocker; ⑤ thiazide; ⑥ mineralocorticoid receptor antagonist.

Renin is an enzyme stored in the juxtaglomerular cells within the afferent arterioles of the kidney. The release of renin is modulated by several factors: intrarenal factors (eg, renal perfusion pressure, catecholamines, angiotensin II) and extrarenal factors (eg, sodium, chloride, potassium).

Juxtaglomerular cells function as a baroreceptor-sensing device. Decreased renal artery pressure and kidney blood flow are sensed by these cells and stimulate renin secretion. A decrease in sodium and chloride delivered to the distal tubule stimulates renin release. Catecholamines increase renin release, most likely by directly stimulating sympathetic nerves on the afferent arterioles that, in turn, activate the juxtaglomerular cells.

Renin catalyzes the conversion of angiotensinogen to angiotensin I in the blood. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). After binding to specific receptors (classified as either angiotensin II type 1 [AT_1] or angiotensin II type 2 [AT_2] subtypes), angiotensin II exerts biologic effects in several tissues. AT_1 receptors are located in the brain, kidneys, myocardium, peripheral vasculature, and adrenal glands. These receptors mediate most responses that are critical to CV and kidney function. AT_2 receptors are located in the adrenal medullary tissue, uterus, and brain. Stimulation of the AT_2 receptor does not influence BP regulation.

Circulating angiotensin II can elevate BP through pressor and volume effects. Pressor effects include direct vasoconstriction, stimulation of catecholamine release from the adrenal medulla, and centrally mediated increases in sympathetic nervous system activity. Angiotensin II also stimulates aldosterone synthesis from the adrenal cortex, leading to sodium and water reabsorption, increasing plasma volume, TPR, and ultimately BP. Aldosterone also has a deleterious role in the pathophysiology of other CV diseases (eg, HF, MI, kidney disease) by promoting tissue remodeling leading to myocardial fibrosis and vascular dysfunction. Clearly, any disturbance that leads to activation of the RAAS could explain chronic hypertension.

Natriuretic Hormone

Natriuretic hormone inhibits sodium and potassium-ATPase and thus interferes with sodium transport across cell membranes. Inherited defects in the kidney’s ability to eliminate sodium can cause increased blood volume. A compensatory increase in the concentration of circulating natriuretic hormone theoretically could increase urinary excretion of sodium and water.

Neuronal Regulation

Central and autonomic nervous systems are intricately involved in the regulation of arterial BP. Many receptors that either enhance or inhibit norepinephrine release are located on the presynaptic surface of sympathetic terminals. The α and β presynaptic receptors play a role in negative and positive feedback to the norepinephrine-containing vesicles. Stimulation of presynaptic α-receptors (α_2) exerts a negative inhibition on norepinephrine release. Conversely, stimulation of presynaptic β-receptors facilitates norepinephrine release.

Sympathetic neuronal fibers located on the surface of effector cells innervate the α- and β-receptors. Stimulation of postsynaptic α-receptors (α_1) on arterioles and venules results in vasoconstriction. There are two types of postsynaptic β-receptors, β_1 and β_2. Both are present in all tissues innervated by the sympathetic nervous system. However, in some tissues, β_1-receptors predominate (eg, heart), and in other tissues, β_2-receptors predominate (eg, bronchioles). Stimulation of β_1-receptors in the heart increases heart rate (chronotropy) and force of contraction (inotropy), whereas stimulation of β_2-receptors causes vasodilation in arteries and veins.

The baroreceptor reflex system is the primary negative feedback mechanism that controls sympathetic activity. Baroreceptors are nerve endings lying in the walls of large arteries, especially in the carotid arteries and aortic arch. Changes in arterial BP rapidly activate baroreceptors that then transmit impulses to the brain stem through the ninth cranial nerve and vagus nerve. In this reflex system, a decrease in arterial BP stimulates baroreceptors, causing reflex vasoconstriction, increased heart rate, and increased force of cardiac contraction. However, baroreceptor reflex mechanisms may be less responsive in older patients and those with diabetes.

Stimulation of specific areas within the central nervous system (eg, nucleus tractus solitarius, vagal nuclei, vasomotor center, area postrema) can either increase or decrease BP. For example, α_2-adrenergic stimulation within the central nervous system decreases BP through inhibitory effects on the vasomotor center. However, angiotensin II increases sympathetic outflow from the vasomotor center, which increases BP.

Neuronal mechanisms regulate BP and maintain homeostasis. Pathologic disturbances in any of the four major components (autonomic nerve fibers, adrenergic receptors, baroreceptors, and central nervous system) could chronically elevate BP. These systems are physiologically interrelated. A defect in one component may alter normal function in another. Therefore, cumulative abnormalities may explain the development of essential hypertension.

Peripheral Autoregulatory Components

Abnormalities in renal or tissue autoregulatory systems could cause hypertension. For example, renal defects in sodium excretion may develop, which can then cause resetting of tissue autoregulatory processes resulting in a higher BP. The kidney usually maintains a normal BP through a volume-pressure adaptive mechanism. When BP drops, the kidneys respond by increasing retention of sodium and water, which leads to plasma volume expansion that increases BP. Conversely, when BP rises above normal, renal sodium and water excretion increase to reduce plasma volume and CO.

Local autoregulatory processes maintain adequate tissue oxygenation. When tissue oxygen demand is normal to low, the local arteriolar bed remains relatively vasoconstricted. However, increased metabolic demand triggers arteriolar vasodilation that lowers peripheral vascular resistance (PVR) and increases blood flow and oxygen delivery.

Defects in renal adaptive mechanisms could lead to plasma volume expansion and increased blood flow to peripheral tissues, even when BP is normal. Local tissue autoregulatory processes that vasoconstrict would then be activated to offset the increased blood flow. This effect would result in increased PVR and, if sustained, would also thicken the arteriolar walls. This pathophysiologic component is plausible because increased TPR is a common underlying finding in essential hypertension.

Vascular Endothelial Mechanisms

Vascular endothelium and smooth muscle play essential roles in regulating blood vessel tone and BP. Regulating functions are mediated by vasoactive substances that are synthesized by endothelial cells. It has been postulated that a deficiency in local synthesis of vasodilating substances (eg, prostacyclin and bradykinin) or excess vasoconstricting substances (eg, angiotensin II and endothelin I) contributes to essential hypertension.

Nitric oxide is produced in the endothelium, relaxes the vascular epithelium, and is a potent vasodilator. The nitric oxide system is an important regulator of arterial BP. Patients with hypertension may have an intrinsic nitric oxide deficiency, resulting in impaired vasodilation.

Electrolytes

Population-based studies demonstrate that high-sodium diets are associated with a high prevalence of stroke and hypertension. Conversely, low-sodium diets are associated with a lower prevalence of hypertension. Clinical studies have shown that dietary sodium restriction lowers BP in many (but not all) patients with elevated BP. The exact mechanisms by which excess sodium leads to hypertension are not known.

Alterations in calcium and potassium may also play an important role in the pathogenesis of hypertension. A lack of dietary calcium hypothetically can disturb the balance between intracellular and extracellular calcium, resulting in an increased intracellular calcium concentration and alterations in vascular smooth muscle function. Dietary potassium intake is inversely related to BP and may blunt the effect of sodium on BP.[1] Potassium depletion may also increase PVR, but the clinical significance of small serum potassium concentration changes in relation to BP is unclear. While altered calcium and potassium may play a role in the development of hypertension, data demonstrating reduced CV risk with supplementation are limited.

CLINICAL PRESENTATION

Diagnostic Considerations

③ Hypertension is called the *silent killer* because most patients do not have symptoms. The primary physical finding is persistently increased BP. The diagnosis of hypertension cannot be made based on one elevated BP measurement. The average of two or more BP measurements taken during two or more clinical encounters is required to diagnose hypertension.[1] This BP average should be used to establish a diagnosis and then classify the initial stage of hypertension using Table 30-3. Out-of-office measurements should be used to confirm elevated readings.

Measuring BP

The measurement of BP is a medical screening tool and should be conducted at every healthcare encounter.[1]

Cuff Measurement

The most common method to measure BP in clinical practice is the indirect measurement of BP using an oscillometric device or sphygmomanometry. The AHA describes the appropriate procedure to measure BP indirectly.[9] The measurement equipment (ie, inflation cuff, stethoscope, and manometer) must meet national standards to ensure maximum quality and precision with measurement.

The AHA stepwise technique is recommended:

1. Patients should ideally refrain from nicotine and caffeine ingestion for 30 minutes, have emptied his/her bladder, and sit with lower back supported in a chair. Their bare arm should be supported and rest near heart level. The feet should be flat on the floor (with legs not crossed). The measurement environment should be relatively quiet and ideally provide privacy. Measuring BP in a position other than seated (supine or standing position) may be required under special circumstances (eg, suspected orthostatic hypotension, dehydration).
2. Measurement should begin only after a 5-minute period of rest in the seated position.
3. Neither the patient nor the clinician measuring the BP should talk during measurement.
4. A properly sized cuff (pediatric, small, regular, large, or extra-large) should be used. The inflatable rubber bladder should cover at least 80% of arm circumference and a width that is at least 40% of arm circumference.
5. The palpatory method should be used to estimate the SBP:
    a. Place the cuff on the upper arm with the bottom resting 2 to 3 cm above the antecubital fossa and attach it to the manometer.
    b. Close the inflation valve and inflate the cuff to 70 mm Hg. Palpate the radial pulse with the index and middle fingers of the opposite hand.
    c. Inflate further in increments of 10 mm Hg until the radial pulse can no longer be palpated.
    d. Note the pressure at which the radial pulse is no longer palpated. This is the estimated SBP.

   e. Rapidly release the pressure in the cuff by opening the valve.

6. The stethoscope (either diaphragm or bell) should be placed on the bare skin of the antecubital fossa, directly over where the brachial artery is palpated. The stethoscope earpieces should be inserted appropriately. The valve should be closed and then the cuff inflated to 30 mm Hg above the estimated SBP from the palpatory method. The valve should then be slightly opened to slowly release pressure at a rate of approximately 2 mm Hg/s.
7. The clinician should listen for Korotkoff sounds with the stethoscope. The first phase of Korotkoff sounds is the initial presence of clear tapping sounds indicating cardiac contraction. Note the pressure at the first recognition of these sounds. This is the SBP. As pressure deflates, note the pressure when all sounds disappear, right at the last sound. This is the DBP.
8. Record the SBP and DBP to the nearest even number (eg, 145 mm Hg rounded up to 146 mm Hg).
9. A second measurement should be obtained after 1 to 2 minutes. If the two measurements (SBP and/or DBP) differ by more than 5 mm Hg, additional measurement(s) should be obtained.
10. When first establishing care with a patient, BP should be measured in both arms. If consistent inter-arm differences exist, the arm with the higher value should be used.

Inaccuracies with indirect measurements result from inherent biologic variability of BP, errors related to incorrect technique, and the white coat effect.[9] Variations in BP occur with environmental temperature, the time of day, meals, physical activity, posture, alcohol, nicotine, and emotions. In the clinical setting, standard BP measurement procedures (eg, appropriate rest period, correct technique, wrong cuff size) are often not followed, which results in incorrect estimation of true BP. In addition, variations may occur between individuals measuring BP. Due to these factors, the use of oscillometric devices is generally preferred.

Approximately 15% to 20% of patients have *white coat hypertension*, where BP values rise in a clinical setting but are normal in nonclinical environments as measured with home or ambulatory BP (ABP) monitors.[1] Interestingly, the rise in BP dissipates gradually after leaving the clinical setting. This is in contrast to *masked hypertension*, where a decrease in BP occurs in the clinical setting.[1] With masked hypertension, home BP is much higher than the in-office BP measurement. This situation may lead to undertreatment or lack of treatment for hypertension. While white coat hypertension is associated with a minimal increase in CV events, masked hypertension increases the risk similar to those with sustained hypertension. Moreover, patients with either white coat or masked hypertension are at higher risk of progressing to sustained hypertension.[10]

Pseudohypertension is a falsely elevated BP measurement. It may be seen in older patients, those with long-standing diabetes, or those with CKD due to rigid, calcified brachial arteries.[9] In these patients, the true arterial BP, when measured directly with intraarterial measurement (the most accurate BP measurement), is much lower than that measured using the indirect cuff method.

Ambulatory and Home BP Monitoring

ABP monitoring using an automated device records BP at frequent time intervals (eg, every 15-30 minutes) throughout a 24-hour period.[9] Home BP monitoring is performed by patients or a caregiver, preferably in the morning. Upper arm devices are preferred over wrist monitors because of concerns regarding the precision of readings. Many wrist monitors are not validated, and positioning of the device (directly over the radial artery) is essential, and the wrist must be placed directly over the heart. However, a validated wrist monitor may be an option for patients whose arm measurements with home devices are difficult or not possible (eg, manual dexterity, extreme obesity). Patients should be counseled to obtain BP monitors that have been validated (see https://www.validatebp.org).

Home BP monitoring values and ABP values are often lower than clinic-measured values, particularly as BP increases beyond elevated to stage 1 and stage 2 hypertension.[1] For example, a clinic BP of 130/80 mm Hg corresponds to a home BP reading of 130/80 mm Hg and a 24-hr ABP of 125/75 mm Hg. However, a clinic BP of 140/90 mm Hg corresponds to a home BP monitoring value of 135/85 mm Hg and a 24-hours ABP value of 130/80 mm Hg.

Neither ABP nor home BP monitoring is needed for the diagnosis of hypertension, but they are recommended. These modalities can enhance the ability to identify patients with white coat and masked hypertension.[1] In addition, ABP monitoring may be a stronger predictor of all-cause and CV mortality than clinic measurements.[11] The 2017 ACC/AHA guideline recommends out-of-office measurements for diagnostic confirmation and to assist in titrating antihypertensive medication.[1] ABP monitoring may be helpful for patients with apparent drug resistance, hypotensive symptoms while on antihypertensive therapy, episodic hypertension (eg, white coat hypertension), and autonomic dysfunction, and in identifying "nondippers" whose BP does not decrease by >10% during sleep and who may portend an increased risk of hypertension-associated complications.

Limitations of ABP and home BP measurements include the complexity of use and costs. Although home BP monitoring is less complicated and less costly than ambulatory monitoring, patients may omit or fabricate readings or have a poor technique (eg, not resting for an adequate period, improper placement, wrong cuff size). Therefore, patients should be educated on the appropriate selection of a home BP device (eg, validated machine, ideally has a memory feature, right cuff size) and how to use it correctly.

Clinical Evaluation

The most common sign of essential hypertension is increased BP. The rest of the physical examination may be completely normal. However, a complete medical evaluation is recommended after diagnosis to (a) identify secondary causes, (b) identify other CV risk factors or comorbid conditions that may define prognosis and/or guide therapy, and (c) assess for the presence or absence of hypertension-associated complications. All patients with hypertension should have the tests described in the Clinical Presentation box before initiating antihypertensive drug therapy.[1] For patients *without* a history of atherosclerotic cardiovascular disease (ASCVD), CKD or diabetes, it is also important to estimate future risk of ASCVD using the Pooled Cohort Equations calculator. This calculator estimates the 10-year risk of clinical ASCVD (defined as coronary death or nonfatal myocardial infarction, or fatal or nonfatal stroke) and lifetime risk in certain patients (found at http://tools.acc.org/ASCVD-Risk-Estimator-Plus/#!/calculate/estimate/).

CLINICAL PRESENTATION: Hypertension

General: May appear healthy or may have additional CV risk factors:

- Age (≥55 years for men, ≥65 years for women)
- Diabetes (type 1 or type 2)
- Dyslipidemia
- Albuminuria
- Family history of premature CV disease
- Overweight (body mass index [BMI] 25-29.9 kg/m^2) or obesity (BMI ≥ 30 kg/m^2)
- Physical inactivity
- Tobacco use

Symptoms: Usually none related to elevated BP.

Signs: Previous BP (SBP or DBP) values in the elevated or the hypertension category.

Routine laboratory tests: Blood urea nitrogen (BUN)/serum creatinine with estimated glomerular filtration rate (using CKD-EPI Creatinine Equation [2021]; available at *https://https://www.kidney.org/professionals/kdoqi/gfr_calculator*), lipid panel, fasting blood glucose, serum electrolytes (sodium, potassium, calcium), hemoglobin and hematocrit, and electrocardiogram. May have normal values and still have hypertension. However, some may have abnormal values consistent with either additional CV risk factors or hypertension-related damage.

Other tests: Echocardiogram, spot urine albumin-to-creatinine ratio, uric acid

Hypertension-related complications: The patient may have a previous medical history or diagnostic findings that indicate the presence of hypertension-associated complications:

- Brain (stroke, transient ischemic attack, dementia)
- Eyes (retinopathy)
- Heart (left ventricular hypertrophy [LVH], angina, prior MI, prior coronary revascularization, HF)
- Kidney (chronic kidney disease [CKD])
- Peripheral vasculature (peripheral arterial disease [PAD])

Secondary Causes

The most common secondary causes of hypertension are listed in Table 30-1. A complete medical evaluation should provide clues for identifying secondary hypertension. Patients with secondary hypertension might have signs or symptoms suggestive of the underlying disorder. Patients with pheochromocytoma may have a history of paroxysmal headaches, sweating, tachycardia, and palpitations. Over half of these patients suffer from episodes of orthostatic hypotension. In primary hyperaldosteronism, symptoms related to hypokalemia usually include muscle cramps and muscle weakness. Patients with Cushing's syndrome may complain of weight gain, polyuria, edema, menstrual irregularities, recurrent acne, or muscular weakness and have several classic physical features (eg, moon face, buffalo hump, hirsutism). Patients with coarctation of the aorta may have higher BP in the arms than in the legs and diminished or even absent femoral pulses. Patients with renal artery stenosis may have an abdominal systolic-diastolic bruit.

Laboratory tests may also help identify secondary hypertension. Baseline hypokalemia may suggest mineralocorticoid-induced hypertension. Protein, red blood cells, and casts in the urine may indicate renovascular disease. Some laboratory tests are used specifically to diagnose secondary hypertension. These include plasma norepinephrine and urinary metanephrine for pheochromocytoma, plasma and urinary aldosterone concentrations for primary hyperaldosteronism, and plasma renin activity, captopril stimulation test, renal vein renin, and renal artery angiography for renovascular disease.

Certain drugs and other products can increase BP (see Table 30-1). For some patients, the addition of these agents can be the cause of hypertension or can exacerbate underlying hypertension. Identifying a temporal relationship between starting the suspected agent and developing elevated BP suggests drug-induced BP elevation.

Natural Course of Disease

The onset of hypertension is usually preceded by increased BP values that are in the elevated BP category. BP values may fluctuate between elevated and normal levels for a period of time. As the disease progresses, PVR increases, and BP elevation becomes chronic.

Hypertension-Associated Complications

Several complications can result from high BP in patients with hypertension (see Clinical Presentation box). CV events (eg, MI, cerebrovascular events, kidney failure) are the primary causes of CV morbidity and mortality in patients with hypertension. The probability of CV events and CV morbidity and mortality in patients with hypertension is directly correlated with the severity of BP elevation.

Hypertension accelerates the development of atherosclerosis and stimulates left ventricular and vascular dysfunction. These pathologic changes are thought to be secondary to both a chronic pressure overload and a variety of nonhemodynamic stimuli. Atherosclerosis in hypertension is accompanied by the proliferation of smooth muscle cells, lipid infiltration into the vascular endothelium, and enhancement of vascular calcium accumulation.

Cerebrovascular disease is a consequence of hypertension. Either gross neurologic deficits or a slight hemiparesis with some incoordination and hyperreflexia is indicative of cerebrovascular disease. Stroke can result from lacunar infarcts caused by thrombotic occlusion of small vessels or intracerebral hemorrhage resulting from ruptured microaneurysms. Transient ischemic attacks (TIAs) secondary to atherosclerosis in the carotid arteries can also develop in patients with hypertension.

Retinopathies can occur in hypertension and may manifest as a variety of different findings. A funduscopic examination can detect hypertensive retinopathy, which manifests as arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes (nicking), retinal hemorrhages and exudates, and disk edema. Focal arteriolar narrowing, retinal infarcts, and flame-shaped hemorrhages usually suggest an accelerated or malignant phase of hypertension (seen in some hypertensive emergencies). Papilledema (swelling of the optic disk) is usually only present in hypertensive emergencies.

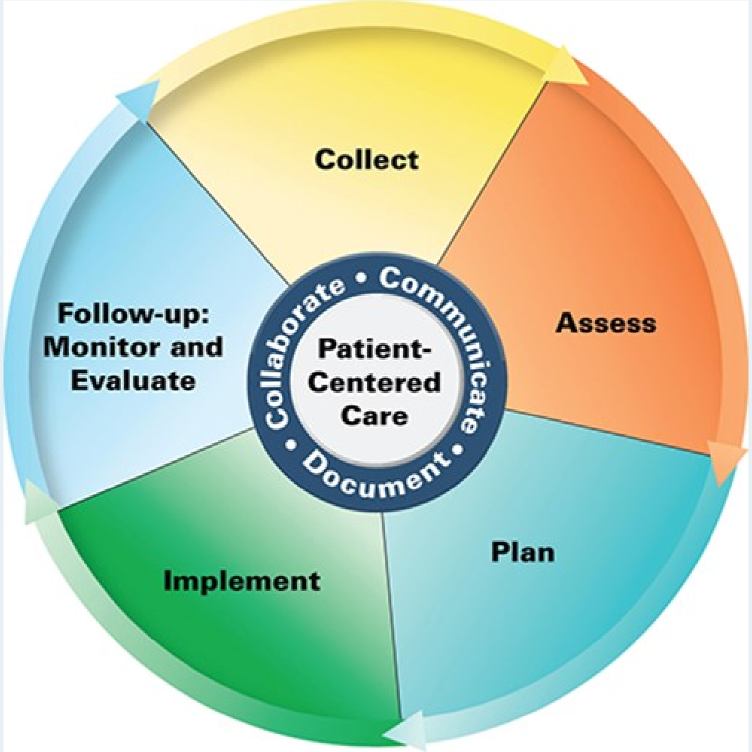
Heart disease is a commonly identified complication of hypertension. A thorough cardiac and pulmonary examination can identify cardiopulmonary abnormalities. Clinical manifestations include stable ischemic heart disease (angina, prior MI, prior coronary revascularization), acute coronary syndromes (aka, acute MI), and HF. These complications may lead to cardiac arrhythmias, angina, MI, and sudden death. Stable ischemic heart disease (also called *coronary artery disease* or *coronary heart disease*) and associated acute coronary syndromes (also called *CV events*) are the most common causes of death in patients with hypertension.

The kidney damage caused by hypertension is characterized pathologically by hyaline arteriosclerosis, hyperplastic arteriosclerosis, arteriolar hypertrophy, fibrinoid necrosis, and atheroma of the major renal arteries. Glomerular hyperfiltration and intraglomerular hypertension are early stages of hypertensive nephropathy, followed by persistent albuminuria and then a gradual decline in kidney function. The primary renal complication in hypertension is nephrosclerosis, which is secondary to arteriosclerosis. Atheromatous disease of a major renal artery may give rise to renal artery stenosis. Overt kidney failure is an important cause of end-stage kidney disease, especially in Black patients, Hispanic persons, and Native Americans.

The peripheral vasculature is a target organ affected by hypertension. Physical examination of the vascular system can detect evidence of atherosclerosis, which may present as arterial bruits (aortic, abdominal, or peripheral), distended veins, diminished or absent peripheral arterial pulses, or lower extremity edema. Peripheral arterial disease (PAD) is a clinical condition that can result from atherosclerosis.

PATIENT CARE PROCESS

Patient Care Process* for the Management of Hypertension



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, pregnant)
- Patient history (past medical, family, social—dietary habits, tobacco use)
- Home blood pressure (BP) readings
- Current medications and prior antihypertensive medication use
- Objective data (see)
  - BP, heart rate (HR), height, weight, and body mass index (BMI)
  - Labs (eg, serum electrolytes, Scr, BUN)
  - Other diagnostic tests when indicated (eg, electrocardiogram [ECG])

Assess

- Presence of compelling indications (eg, stable ischemic heart disease, chronic kidney disease; see Fig. 30-3)
- Hypertension-related complications (eg, albuminuria, retinopathy; see)
- 10-year atherosclerotic cardiovascular disease (ASCVD) risk when indicated
- Current medications that may contribute to or worsen hypertension

- BP goal and whether the goal has been achieved (see)
- Appropriateness and effectiveness of the current antihypertensive regimen
- For resistant hypertension if taking three or more antihypertensive medications (see Table 30-8)

Plan*

- Tailored lifestyle modifications (eg, diet, exercise, weight management; see Table 30-4)
- Drug therapy regimen including specific antihypertensive(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 30-5, 30-6, 30-7, and 30-9)
- Monitoring parameters including efficacy (eg, BP, CV events, kidney health), safety (medication-specific adverse effects), and timeframe (see Table 30-10)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy)
- Self-monitoring of BP, HR, and weight—where and how to record results
- Referrals to other providers when appropriate (eg, physician, dietician)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Determine BP goal attainment
- Presence of adverse effects
- Occurrence of CV events and development/progression of kidney impairment
- Patient adherence to treatment plan using multiple sources of information

** Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Overall Goal of Treatment

④ The overall goal of treating hypertension is to reduce morbidity and mortality from CV events (eg, acute coronary syndromes, cerebrovascular events, HF) and kidney disease. Therefore, the specific selection of antihypertensive drug therapy should be based on evidence demonstrating a reduction in morbidity and mortality, not merely a reduction in BP.

Blood Pressure Goals

⑤ Treating patients with hypertension to achieve a desired goal BP is a surrogate goal of therapy. Reducing BP to a goal does not guarantee the prevention of hypertension-associated complications but significantly lowers risk. Targeting a goal BP is the standard of care for how clinicians evaluate response to therapy. It is the primary method used to determine the need for titration and regimen modification.

The 2017 ACC/AHA guideline recommends a goal BP of <130/80 mm Hg for the management of hypertension in most patients (Box A), including those with ASCVD, diabetes, or chronic kidney disease.[1] The American Diabetes Association recommends a minimum goal of <140/90 mm Hg for patients with diabetes and lowers CV risk, with a lower goal of <130/80 mm Hg for certain individuals (eg, those at higher risk of ASCVD) if achieved without undue treatment burden.[12] The Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend an SBP goal of <120 mm Hg for patients with CKD (not receiving dialysis) when tolerated.[13]

Box A
Desired Outcomes: Goal BP for Chronic Treatment

Most patients (includes patients with clinical ASCVD [secondary prevention], diabetes, or CKD; primary prevention patients regardless of 10-year ASCVD risk score)

- <130/80 mm Hg

Older ambulatory, community-dwelling patients

- SBP <130 mm Hg

Institutionalized older patients, those with high disease burden and comorbidities, or limited life-expectancy:

- Consider a relaxed SBP goal of at least <150 mm Hg; <140 mm Hg in some patients if tolerated
- Use a team-based decision process weighing patient preferences, risks, and benefits

Historically, most patients with hypertension were treated to a goal BP of <140/90 mm Hg, with <130/80 mm Hg recommended for higher-risk patients. However, evidence demonstrates a significantly lower risk of CV events with lower BP goals. Some of the strongest data supporting the lower BP goals comes from the Systolic Blood Pressure Intervention Trial (SPRINT). SPRINT evaluated a systolic BP goal of <120 mm Hg versus <140 mm Hg in patients with hypertension at high CV risk but without diabetes.[14] The study was stopped early after a median follow-up of 3.3 years due to a significantly lower risk of the primary composite outcome (MI, other acute coronary syndromes, stroke, HF, or death from CV causes) and all-cause mortality in patients treated to the lower BP goals. The final results when the trial was fully adjudicated were consistent with the initially published report.[15] Despite an increased risk of adverse events in the intensive treatment group (eg, hypotension, syncope, electrolyte abnormalities, and acute kidney injury or failure), the significant benefits outweighed these risks, with intensive BP control improving survival by 6 months to 3 years in middle-aged and older adults with high CV risk.[16]

In addition to SPRINT, several other systematic reviews and meta-analyses demonstrate that lower BP goals improve clinical outcomes better than higher BP goals.[17–21] In a systematic review and meta-analysis of 19 trials involving 44,989 patients, intensive treatment (mean BP 133/76 mm Hg) was associated with a reduced risk of major CV events, MI, stroke, albuminuria, and retinopathy progression compared to less intensive BP-lowering (mean BP 140/81 mm Hg).[18] The risk of serious adverse events with intensive therapy was low and did not differ significantly compared to less-intensive treatment, though severe hypotension was more frequent.

BP goal values for patients with diabetes have been a subject of debate for a number of years. A BP goal of <130/80 mm Hg was historically recommended for patients with diabetes by multiple organizations. The primary evidence supporting this recommendation was from the Hypertension Optimal Treatment (HOT) study, which compared diastolic BP goals of <90, <85, or <80 mm Hg on CV outcomes.[22] Only the subgroup of patients with diabetes (n = 1,501) had a lower risk of major CV events in the <80 mm Hg group versus the <90 mm Hg group.

However, the NHLBI-sponsored Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD-BP) study questioned the benefit of lower BP goals for patients with diabetes.[23] The ACCORD-BP was an open-label, factorial study that randomized 4,733 patients with type 2 diabetes to an SBP of <120 or <140 mm Hg. After a mean follow-up of 4.7 years, there was no significant difference in the annual rate of the primary endpoint (nonfatal MI, nonfatal stroke, or CV death) between the two groups. However, the annual incidence of the secondary endpoint of stroke was significantly lower with the <120 mm Hg goal. Also, there are significant limitations to ACCORD-BP. First, ACCORD-BP was underpowered, as only half of the expected primary composite endpoint events occurred during the study. It was also a factorial study design. A posthoc analysis of ACCORD-BP that examined CV outcomes for participants with CVD risk factors that would have been eligible for SPRINT found similar CV event rates and adverse effect rates as seen in SPRINT.[24] Also, the evidence-based review performed for the 2017 ACC/AHA guideline found a lower risk of fatal or nonfatal stroke with lower BP goals in patients with diabetes.[17] Therefore, most patients with diabetes should be treated to a BP of <130/80 mm Hg.

Avoiding Clinical Inertia

Although hypertension is one of the most common medical conditions, BP control rates are poor. *Clinical inertia* in hypertension is defined as an office visit for which no therapeutic move was made to lower BP in a patient with uncontrolled hypertension.[25] Clinical inertia is not the entire reason why many patients with hypertension do not achieve goal BP values. However, it is a major reason that can be remedied simply through more aggressive antihypertensive drug therapy. This strategy can include initiating, titrating, or changing drug therapy.

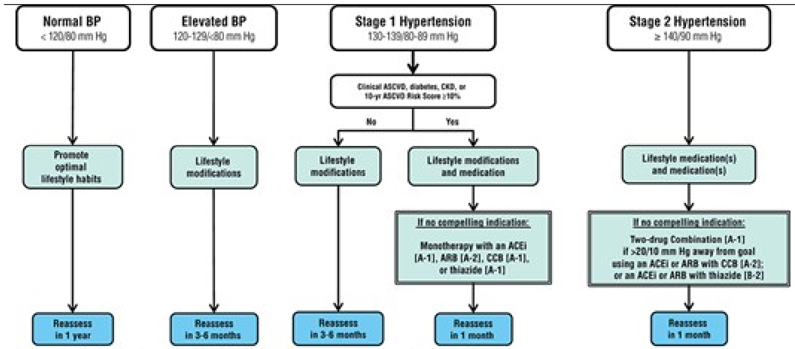
General Approach to Treatment

All patients with elevated blood pressure, stage 1 hypertension, and stage 2 hypertension should be engaged in lifestyle modifications. For patients with elevated blood pressure and those with stage 1 hypertension who are at low risk of ASCVD (ie, primary prevention, without CKD, without diabetes but with a 10-year ASCVD risk <10%), lifestyle modification alone is an appropriate initial treatment. The *threshold* for when these low-risk patients should start drug therapy is when the BP is ≥140/90 mm Hg with a *goal* BP of <130/80 mm Hg. For patients with stage 1 or 2 hypertension who already have ASCVD (secondary prevention) or who have an elevated 10-year ASCVD risk ≥10% (including patients with diabetes and patients with CKD), the *threshold* for starting drug therapy is ≥130/80 mm Hg with a *goal* BP of <130/80 mm Hg.

⑥ The choice of initial antihypertensive drug therapy depends on the degree of BP elevation and presence of compelling indications (see 9.5 section). A single first-line antihypertensive drug should be started as initial therapy in most patients with newly diagnosed stage 1 hypertension. Combination drug therapy, preferably with two first-line antihypertensive drugs, should be started as initial therapy in patients with newly diagnosed hypertension presenting with more severe BP elevation (stage 2 hypertension). This general approach to initial therapy is outlined in Fig. 30-2. There are several compelling indications where specific antihypertensive drug classes have evidence showing unique benefits in patients with hypertension (see Fig. 30-3). Under these circumstances, the selection of antihypertensive drug therapy should follow an evidence-based order.

FIGURE 30-2

Algorithm for treatment of elevated BP and hypertension based on BP category at initial diagnosis. Drug therapy recommendations are graded with the strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendations, respectively. Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled studies, or dramatic results from uncontrolled experiments or subgroup analyses; (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. *Monotherapy with an ACEi, ARB, CCB, or thiazide is appropriate in patients presenting in Stage 2 hypertension if they are at high risk for orthostatic hypertension or are very elderly.



Normal BP
< 120/80 mm Hg
Elevated BP
120-129/<80 mm Hg
Stage 1 Hypertension
130-139/80-89 mm Hg
Stage 2 Hypertension
≥ 140/90 mm Hg
Clinical ASCVD, diabetes, CKD, or 10-yr ASCVD Risk Score ≥10%
No
Yes
Promote optimal lifestyle habits
Lifestyle modifications
Lifestyle modifications
Lifestyle modifications and medication
Lifestyle medication(s) and medication(s)
If no compelling indication:
Monotherapy with an ACEi [A-1], ARB [A-2], CCB [A-1], or thiazide [A-1]
If no compelling indication:
Two-drug Combination [A-1] if >20/10 mm Hg away from goal using an ACEi or ARB with CCB [A-2]; or an ACEi or ARB with thiazide [B-2]
Reassess in 1 year
Reassess in 3-6 months
Reassess in 3-6 months

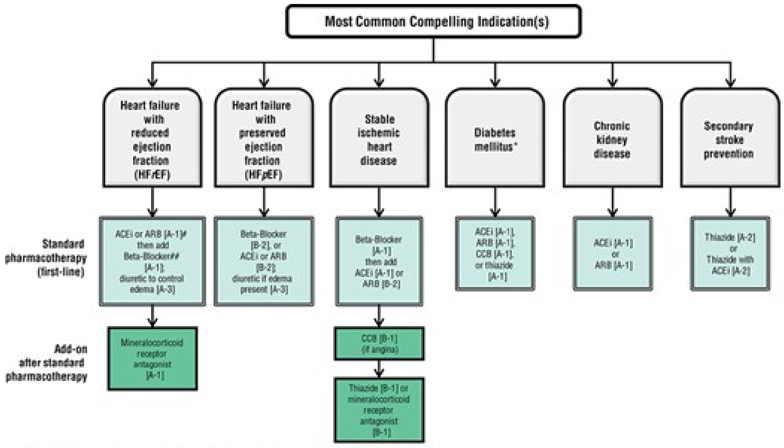
FIGURE 30-3

The most common compelling indications for individual drug classes. Compelling indications for specific drugs are evidenced-based recommendations from outcome studies or existing clinical guidelines. The order of drug therapies serves as a general guidance that should be balanced with clinical judgment and patient response. Add-on pharmacotherapy recommendations are when additional medications are needed to lower blood pressure to goal. Blood pressure control should be managed concurrently with the compelling indication. Drug therapy recommendations are graded with the strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendations, respectively. Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments or subgroup analyses; (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. #An ARB with an angiotensin receptor neprilys inhibitor preferred aheadof an ACEi or ARB for the treatment of HFrEF. ##In HFrEF only, use bisprolol, carvedilol, or metoprolol succinate, titrated to the evidence based dose. *If albuminuria present in diabetes, treat like chronic kidney disease and use an ACEi or ARB titrated to the maximum tolerated dose.



Most Common Compelling Indication(s)
Heart failure with reduced ejection fraction (HFrEF)
Heart failure with preserved ejection fraction (HFpEF)
Stable ischemic heart disease
Diabetes mellitus*
Chronic kidney disease
Secondary stroke prevention
Standard pharmacotherapy (first-line)
ACEi or ARB [A-1]# then add Beta-Blocker## [A-1]; diuretic to control edema [A-3]
Beta-Blocker [B-2], or ACEi or ARB [B-2]; diuretic if edema present [A-3]
Beta-Blocker [A-1] then add ACEi [A-1] or ARB [B-2]
ACEi [A-1], ARB [A-1], CCB [A-1], or thiazide [A-1]
ACEi [A-1] or ARB [A-1]
Thiazide [A-2] or Thiazide with ACEi [A-2]
Add-on after standard pharmacotherapy
Mineralocorticoid receptor antagonist [A-1]
CCB [B-1] (if angina)
Thiazide [B-1] or mineralocorticoid receptor antagonist [B-1]

Nonpharmacologic Therapy

7 All patients with elevated blood pressure and hypertension should be prescribed lifestyle modifications. However, they should never be used to replace antihypertensive drug therapy for patients with hypertension who are not at goal BP. Recommended nonpharmacological treatments that have been shown to lower BP are listed in Table 30-4.[1] Lifestyle modifications can provide small to moderate reductions in SBP. Aside from reducing BP in patients with known hypertension, strict adherence to lifestyle modification can decrease the progression to hypertension in patients with elevated BP values, and improve other aspects of CV health (eg, cholesterol, weight).

TABLE 30-4

Lifestyle Modifications to Prevent and Manage Hypertension[a]

Modification	Recommendation	Approximate SBP Reduction (mm Hg)	
		With Hypertension	Without Hypertension
Weight loss	Maintain normal body weight (body mass index, 18.5-24.9 kg/m^2), but aim for at least ≥1 kg weight reduction. Approximate 1 mm Hg BP reduction noted per 1 kg weight loss.	5	2-3
DASH-type dietary patterns	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	11	3
Reduced salt intake	Reduce daily dietary sodium intake as much as possible, ideally to 1.5 g/day sodium (3.8 g/day sodium chloride)	5-6	2-3
Physical activity	90-150 min/wk of aerobic or dynamic resistance training, and involving moderate- to-vigorous intensity[b]	• 5-8 aerobic • 4 dynamic	• 2-4 aerobic • 2 dynamic
Moderation of alcohol intake	Limit consumption to ≤2 drink equivalents per day in men and ≤1 drink equivalent per day in women and lighter-weight persons[c]	4	3

[a] Effects of implementing these modifications are time- and dose-dependent and could be greater for some patients.

[b] Aerobic exercise at 65%-75% heart rate reserve; dynamic resistance consisting of 6 exercises, 3 sets/exercise, 10 repetitions/set at 50%-80% of 1 rep maximum.

[c] One drink equivalent is equal to 1.5 oz (~45 mL) of 80-proof distilled spirits (eg, whiskey), a 5 oz (~150 mL) glass of wine (12%), or 12 oz (~350 mL) of beer.

A sensible dietary program is designed to reduce weight gradually for overweight and obese patients and restricts sodium intake with limited alcohol consumption (for patients who consume alcohol). Patients' successful implementation of dietary and lifestyle modifications requires aggressive promotion by clinicians through patient education, encouragement, and continued reinforcement. Weight loss, as little as 5% of body weight, can decrease BP significantly in overweight or obese patients. Diets rich in fruits and vegetables and low in saturated fat have been shown to lower BP in patients with hypertension.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat. It is an evidence-based diet that lowers BP. Intake of sodium should be minimized as much as possible, ideally to 1.5 g/day, although an interim goal of a 1 g/day reduction may be reasonable considering the challenges in achieving low sodium intake. Patients should be aware of the multiple sources of dietary sodium (eg, processed foods, soups, table salt) so that they may implement the restriction. Potassium intake should be encouraged through fruits and vegetables with a high content (ideally 3,500-5,000 g/day) in those with normal kidney function or without impaired potassium excretion. Excessive alcohol use can either cause or worsen hypertension. Patients with hypertension who drink alcoholic beverages should restrict their daily intake.

Physical activity consisting of aerobic or dynamic resistance training of 90 to 150 min/week (eg, 3-4 sessions/week, lasting on average 40 min/session) and involving moderate-to-vigorous intensity should be encouraged when possible. Studies have shown that physical activity, and in particular aerobic activity, can reduce BP, even in the absence of weight loss. Patients should consult their physicians before starting an exercise program, especially those with hypertension-associated complications.

Smoking (tobacco or other products) is not a secondary cause of essential hypertension. However, smoking is a major, independent, modifiable risk factor for CV disease. Therefore, while smoking cessation is not a recommended strategy to control BP, patients with hypertension who smoke should be counseled regarding the additional health risks that result from smoking and be encouraged to quit.

Pharmacologic Therapy

8 An ACEi, ARB, CCB, or thiazide are preferred first-line antihypertensive agents for most patients (Table 30-5).[1] These agents should be used to treat the majority of patients with hypertension because of evidence demonstrating CV event reduction. Several of these medications have subclasses where significant differences in the mechanism of action, clinical use, side effects, or evidence from outcome studies exist. β-Blocker therapy should be reserved to treat a specific, compelling indication or may be used in combination with one or more first-line antihypertensive agents for patients without a compelling indication. Other antihypertensive drug classes are considered alternative drug classes that should be limited for use in select patients after implementing first-line agents (Table 30-6).

TABLE 30-5

Most Common First-Line and Other Antihypertensive Agents

Class	Subclass	Medication (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
ACEi		Benazepril (Lotensin)	10-40	1 or 2	May cause hyperkalemia in patients with chronic kidney disease or in those receiving a potassium-sparing diuretic, or MRA; should not be used in combination with an ARB, or direct renin inhibitor; can cause acute kidney injury in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; contraindicated in pregnancy or in patients with a history of angioedema; starting dose should be reduced 50% in patients who are on a thiazide, are volume depleted, or are very elderly due to risks of hypotension.
		Captopril (Capoten)	12.5-150	2 or 3	
		Enalapril (Vasotec)	5-40	1 or 2	
		Fosinopril (Monopril)	10-40	1	
		Lisinopril (Prinivil, Zestril)	10-40	1	
		Moexipril (Univasc)	7.5-30	1 or 2	
		Perindopril (Aceon)	4-16	1	
		Quinapril (Accupril)	10-80	1 or 2	
		Ramipril (Altace)	2.5-10	1 or 2	
		Trandolapril (Mavik)	1-4	1	
ARB		Azilsartan (Edarbi)	40-80	1	May cause hyperkalemia in patients with chronic kidney disease or in those receiving a potassium-sparing diuretic, or MRA; should not be used in combination with an ACEi or direct renin inhibitor; can cause acute kidney injury in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not cause a dry cough like an ACEi may; contraindicated in pregnancy; starting dose should be reduced 50% in patients
		Candesartan (Atacand)	8-32	1 or 2	
		Eprosartan (Teveten)	600-800	1 or 2	
		Irbesartan (Avapro)	150-300	1	
		Losartan (Cozaar)	50-100	1 or 2	

		Telmisartan (Micardis)	20-40	1	who are on a thiazide, are volume depleted, or are very elderly due to risks of hypotension.
		Olmesartan (Benicar)	20-80	1	
		Valsartan (Diovan)	80-320	1	
Calcium channel blocker	Dihydropyridine	Amlodipine (Norvasc)	2.5-10	1	Do not use immediate-release nifedipine or immediate-release nicardipine; dihydropyridines are more potent arterial vasodilators than nondihydropyridines and may cause more peripheral edema; may cause reflex sympathetic discharge (tachycardia); have additional benefits in Raynaud's syndrome.
		Felodipine (Plendil)	5-20	1	
		Nifedipine long-acting (Afeditab CR Adalat CC, Nifediac CC, Nifedical XL, Procardia XL)	30-90	1	
		Nisoldipine (Sular)	10-40	1	
	Nondihydropyridine	Diltiazem sustained release (Cardizem CD, Cartia XT, Dilacor XR, Diltia XT, Tiazac, Taztia XT)	120-480	1	Use extended-release products for hypertension; these agents block the A-V node, reduce heart rate, and may produce heart block, especially in combination with β-blockers; not all products are not AB rated as interchangeable on an equipotent milligram-per-milligram basis due to different release mechanisms and bioavailability; Cardizem LA, Matzim LA, and Verelan PM have delayed drug release for several hours after dosing and can provide chronotherapeutic drug delivery, but this does not have any clinical advantages; have additional benefits in patients with atrial tachyarrhythmia.
		Diltiazem extended release (Cardizem LA, Matzim LA)	180-480	1 (morning or evening)	
		Verapamil sustained release (Calan SR, Isoptin SR, Verelan)	180-420	1 or 2	
		Verapamil chronotherapeutic oral drug absorption system (Verelan PM)	100-400	1 (in the evening)	
Diuretic	Thiazide	Chlorthalidone (Thalitone)	12.5-25	1	Hydrochlorothiazide is a "thiazide-type" while chlorthalidone, indapamide, and metolazone are "thiazide-like." Dose in the morning to avoid nocturnal diuresis; thiazides are more effective antihypertensives than loop diuretics in most patients; use usual doses to avoid adverse metabolic effects; hydrochlorothiazide, chlorthalidone, and indapamide are preferred; chlorthalidone is approximately 1.5 times as potent as hydrochlorothiazide; have additional benefits in osteoporosis; use with caution in patients with a history of gout.
		Hydrochlorothiazide (Microzide)	12.5-50	1	
		Indapamide (Lozol)	1.25-2.5	1	
		Metolazone (Zaroxolyn)	2.5-10	1	
	Loop	Bumetanide (Bumex)	0.5-4	2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; higher doses may be needed for patients with severely decreased glomerular filtration rate or HF; preferred over thiazides in patient with severe kidney dysfunction and resistant hypertension.
		Furosemide (Lasix)	20-80	2	
		Torsemide (Demadex)	5-10	1	

	Potassium-sparing	Amiloride (Midamor)	5-10	1 or 2	Weak diuretics that are used in combination with a thiazide to minimize hypokalemia; do not significantly lower BP unless used with a thiazide; should be reserved for patients experiencing diuretic-induced hypokalemia; avoid in patients with severe chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73m^2); may cause hyperkalemia, especially in combination with a mineralocorticoid receptor antagonist, ACEi, ARB, direct renin inhibitor, or potassium supplements.
		Amiloride/hydrochlorothiazide (Moduretic)	5/50	1	
		Triamterene (Dyrenium)	50-100	1 or 2	
		Triamterene/hydrochlorothiazide (Dyazide, Maxide)	37.5-75/25-50	1	
	MRA	Eplerenone (Inspra)	50-100	1 or 2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; eplerenone contraindicated in patients with an estimated creatinine clearance <50 mL/min (0.83 mL/s), elevated serum creatinine (>1.8 mg/dL [115 µmol/L] in women, >2 mg/dL [177 µmol/L]) in men), and type 2 diabetes with albuminuria; often used as add-on therapy in resistant hypertension; avoid in patients with severe chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73m^2); may cause hyperkalemia, especially in combination with an ACEi, ARB, direct renin inhibitor, or potassium supplements.
		Spironolactone (Aldactone, CaroSpir)	25-50	1 or 2	
β-Blocker	Cardioselective	Atenolol (Tenormin)	25-100	1 or 2	Abrupt discontinuation may cause rebound hypertension; have additional benefits in patients with atrial tachyarrhythmia or preoperative hypertension; in general, cardioselective agents inhibit β_1-receptors at low to moderate dose, higher doses may also block β_2-receptors (especially metoprolol); additional vasodilation with nebivolol does not result in more orthostatic hypotension; nonselective agents inhibit β_1- and β_2-receptors at all doses, can exacerbate asthma, and have additional benefits in patients with essential tremor, migraine headache, portal hypertension, thyrotoxicosis. Agents with intrinsic sympathomimetic activity (acebutolol and pindolol) partially stimulate β-receptors while blocking against additional stimulation; no role in the management of hypertension and are contraindicated in patients with stable ischemic heart disease. Mixed α- and β-blockers produces vasodilation and have more orthostatic hypotension.
		Betaxolol (Kerlone)	5-20	1	
		Bisoprolol (Zebeta)	2.5-10	1	
		Metoprolol tartrate (Lopressor)	100-200	2	
		Metoprolol succinate extended release (Toprol XL)	50-200	1	
		Nebivolol (Bystolic)	5-20	1	
	Nonselective	Nadolol (Corgard)	40-120	1	
		Propranolol (Inderal)	160-480	2	
		Propranolol long acting (Inderal LA, Inderal XL, InnoPran XL)	80-320	1	
		Timolol (Blocadren)	10-40	1	
	Mixed α- and β-blockers	Carvedilol (Coreg)	12.5-50	2	

		Carvedilol phosphate (Coreg CR)	20-80	1	
		Labetalol (Normodyne, Trandate)	200-800	2	

TABLE 30-6

Alternative Antihypertensive Agents

Class	Medication (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
α_1-Blocker	Doxazosin (Cardura)	1-8	1	Give first dose at bedtime; patients should rise from sitting or lying down slowly to minimize risk of orthostatic hypotension; additional benefits in men with benign prostatic hyperplasia
	Prazosin (Minipress)	2-20	2 or 3	
	Terazosin (Hytrin)	1-20	1 or 2	
Direct renin inhibitor	Aliskiren (Tekturna)	150-300	1	May cause hyperkalemia in patients with chronic kidney disease and diabetes or in those receiving a potassium-sparing diuretic, MRA; do not use in combination with an ACEi or ARB; may cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy
Central α_2-agonist	Clonidine (Catapres)	0.1-0.8	2	Oral form should be avoided due to need for frequent administration and potential rebound HTN with abrupt discontinuation or nonadherence; most effective if used with a thiazide to diminish fluid retention; clonidine patch is replaced once per week
	Clonidine patch (Catapres-TTS)	0.1-0.3	1 weekly	
	Methyldopa (Aldomet)	250-1,000	2	
Direct arterial vasodilator	Minoxidil (Loniten)	10-40	1 or 2	Should be used with thiazide and β-blocker to diminish fluid retention and reflex tachycardia
	Hydralazine (Apresoline)	20-100	2 to 4	

Historical Evidence Supporting Thiazide Therapy

Landmark placebo-controlled clinical trials demonstrate that thiazide therapy irrefutably reduces the risk of CV morbidity and mortality. The Systolic Hypertension in the Elderly Program (SHEP),[6] Swedish Trial in Old Patients with Hypertension (STOP-Hypertension),[5] and Medical Research Council

(MRC)[7] studies showed significant reductions in stroke, MI, all-cause CV disease, and mortality with a thiazide-based therapy versus placebo. These trials allowed for β-blockers as add-on therapy for BP control. Agents such as an ACEi, ARB, and CCB were not available at the time of these studies. However, subsequent clinical trials have compared these antihypertensive agents with a thiazide and have demonstrated similar long-term benefits.[26–32]

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)

The results of the ALLHAT were the deciding evidence that prior guidelines used to justify thiazide therapy as first-line therapy.[26] It was designed to test the hypothesis that newer antihypertensive agents (an α-blocker, ACEi, or dihydropyridine CCB) would be superior to thiazide-based therapy. The primary objective was to compare the combined endpoint of fatal CHD and nonfatal MI. Other hypertension-related complications (eg, HF, stroke) were evaluated as secondary endpoints. This was the largest prospective hypertension trial ever conducted and included 42,418 patients aged 55 years and older with hypertension and one additional CV risk factor. This double-blind trial randomized patients to chlorthalidone-, amlodipine-, doxazosin-, or lisinopril-based therapy for a mean of 4.9 years.

The doxazosin treatment arm was terminated early when a significantly higher risk of HF versus chlorthalidone was observed.[33] The other arms were continued as scheduled, and no significant differences in the primary endpoint were seen between the chlorthalidone and lisinopril or amlodipine treatment groups at the end of the trial. However, chlorthalidone had fewer secondary endpoints than amlodipine (HF) and lisinopril (combined CV disease, HF, and stroke). The study conclusions were that chlorthalidone-based therapy was superior in preventing one or more major forms of CV disease and was less expensive than amlodipine- or lisinopril-based therapy.

ALLHAT was designed as a superiority study with the hypothesis that amlodipine, doxazosin, and lisinopril would be better than chlorthalidone.[34] It did not prove this hypothesis. Several subgroup analyses of specific populations (eg, Black patients, CKD, diabetes) from the ALLHAT have been conducted to assess response in certain unique patient populations.[35–37] Surprisingly, none of these analyses demonstrated superior CV event reductions with lisinopril or amlodipine versus chlorthalidone. Overall, thiazides remain unsurpassed in their ability to reduce CV morbidity and mortality in most patients.

The 2017 ACC/AHA high BP guideline recommends a thiazide as first-line therapy for most patients.[1] However, an ACEi, ARB, or CCB are also comparable first-line options. Contrary to the historical preference to use a thiazide as preferred for treating most patients with hypertension, they are simply one of the four first-line drug therapy options. Figure 30-2 displays the algorithm for treating hypertension and highlights the four first-line antihypertensive options for patients without a compelling indication for a specific drug class.

ACEi, ARB, and CCB as First-Line Agents

Clinical trial data cumulatively demonstrate that ACEi–, CCB-, or ARB-based antihypertensive therapy reduces CV events. These agents are first-line options for patients without a compelling indication. The Blood Pressure Lowering Treatment Trialists' Collaboration has evaluated the incidence of major CV events and death among different antihypertensive drug classes from 29 major randomized trials in 162,341 patients.[38] In placebo-controlled trials, major CV events were significantly lower with ACEi-– and CCB-based regimens versus placebo. Although there were minor differences in the incidence of certain CV events in some comparisons, there were no differences in total major CV events when an ACEi, CCB, or thiazide was compared with each other. In studies evaluating ARB-based therapy to control regimens, the incidence of major CV events was lower with ARB-based therapy. However, the control regimens used in these comparisons included both antihypertensive drug therapies and placebo. These results were largely consistent with the network meta-analysis conducted for the 2017 ACC/AHA guideline, which found that an ACEI, ARB, CCB, or thiazide were all similar as first-line treatment for hypertension.[17]

Data from meta-analyses that incorporate high-quality randomized controlled trials provide more robust data than any single trial alone. High-quality meta-analyses are considered the highest level of evidence by the ACC/AHA guidelines and provide clinically useful data that support using ACEi-, CCB-, or ARB-based treatment for hypertension as first-line antihypertensive agents. Clinicians should use meta-analyses data as supporting evidence when selecting a first-line antihypertensive regimen for hypertension in most patients.

β-Blocker Versus First-Line Agents

9 Clinical trial data and meta-analyses cumulatively suggest that treatment with a β-blocker may reduce CV events better than placebo but not to the extent that an ACEi, ARB, CCB, or particularly thiazide diuretics do.[1] In the systematic review and network analysis conducted for the 2017 ACC/AHA guideline, β-blockers were less effective for preventing stroke and CV events than diuretics.[17]

Meta-analyses data evaluating β-blockers and their ability to reduce CV events have limitations. Most studies that were included in these analyses used atenolol as the β-blocker studied. Therefore, it is possible that atenolol is inferior and is the only β-blocker that does not reduce CV events as much as other first-line antihypertensive drug classes. A network meta-analysis comparing the effects of different β-blockers found a decreased risk of mortality and CV events with lipophilic agents (metoprolol, propranolol, and oxprenolol) compared to hydrophilic agents (atenolol).[39] However, due to challenges in the interpretation of meta-analyses of β-blockers compared to other first-line agents (eg, trials conducted at different times, use of different beta-blockers, changes in the efficacy of agents), most guideline recommendations do not differentiate between the β-blocker drug class. In the absence of a compelling indication, a β-blocker can be considered only after other first-line antihypertensive agents (ACEi or ARB, CCB, thiazide) have been used.[1,40] These findings also call into question the validity of results from prominent prospective, controlled clinical trials evaluating antihypertensive drug therapy that used β-blocker–based therapy, especially atenolol, as the primary comparator.[28,30] These studies used once-daily atenolol, which in addition to being hydrophilic, may have been inadequately dosed based on the short half-life of this agent.

β-Blocker–based antihypertensive therapy does not increase the risk of CV events; β-blocker–based therapy reduces the risk of CV events compared with no antihypertensive therapy. Using a β-blocker as a first-line antihypertensive agent is an option when an ACEi, ARB, CCB, or thiazide cannot be used. β-Blockers also have an important role as add-on therapy to first-line agents to reduce BP in patients with hypertension but without compelling indications.

Many of the clinical trials included in the meta-analyses suggest that β-blocker–based therapy may not reduce CV events as well as these other agents, used atenolol dosed once daily.[41] Atenolol has a half-life of 6 to 7 hours and is nearly always dosed once daily, while immediate-release forms of carvedilol and metoprolol have half-lives of 6 to 10 and 3 to 7 hours, respectively, and are dosed at least twice daily.[41] It is also hydrophilic, which may not penetrate the brain and cell membrane as easily as lipophilic agents, and is inferior to lipophilic agents (metoprolol, propranolol, and oxprenolol).[39] Therefore, it is possible that these findings might only apply to atenolol, particularly dosed once daily instead of twice daily. Based on available evidence, metoprolol succinate or carvedilol are the preferred β-blockers if a β-blocker is to be used.

Patients with Compelling Indications

10 Compelling indications represent specific comorbid conditions where evidence from clinical trials supports using specific antihypertensive classes to treat both the compelling indication and hypertension. Antihypertensive medication recommendations typically consist of combination drug therapy (see Fig. 30-3). Data from clinical trials have demonstrated a reduction in CV morbidity and/or mortality that justifies use for patients with hypertension and with such a compelling indication.

Heart Failure with Reduced Ejection Fraction

Five drug classes have compelling indications for HF with reduced ejection fraction (HFrEF), also known as systolic HF or left ventricular dysfunction.[42] The primary physiologic abnormality in HFrEF is decreased CO resulting from a decreased left ventricular ejection fraction. An evidence-based pharmacotherapy regimen for HFrEF, called *guideline-directed medical therapy*, consists of three to four drugs: an ACEi or ARB (although ARB with a neprilysin inhibitor [aka angiotensin receptor neprilysin inhibitor; ARNI] is preferred ahead of an ACEi or ARB alone according to HFrEF recommendations), an evidence-based β-blocker (ie, bisoprolol, carvedilol, metoprolol succinate) titrated to the maximum dose, and then possibly an MRA.[43] Diuretics are often needed in patients with HFrEF primarily to provide symptomatic relief of edema by inducing diuresis. Loop diuretics are often needed, especially for patients with more advanced HF and/or advanced stages of CKD. However, some patients with well-controlled HF and without significant CKD may be managed with a thiazide.

For patients with hypertension and HFrEF full implementation for guideline-directed medical therapy to treat HFrEF using multiple pharmacologic therapies should be the primary driver of pharmacotherapy. When done correctly and completely, not only are benefits related to HFrEF realized but lowering of BP to goal is usually achieved.

β-Blocker therapy modifies disease in HFrEF and is a component of standard treatment for these patients. For patients on an initial regimen of a diuretic with an ACEi or ARB (or ARNI), add-on β-blocker therapy has been shown to reduce CV morbidity and mortality.[42,44] It is of paramount importance that β-blockers be dosed appropriately due to the risk of inducing an acute exacerbation of HF. They must be started in low doses (much lower than that used to treat hypertension) and titrated slowly to high doses based on tolerability. Bisoprolol, carvedilol, and metoprolol succinate are the only β-blockers that are proved to be beneficial in HFrEF.

After implementing a standard HFrEF regimen (diuretic, ACEi or ARB alone [or ARNI], and evidence-based β-blocker), other agents may be added to reduce CV morbidity and mortality further and reduce BP if needed. The addition of a mineralocorticoid receptor antagonist (spironolactone or eplerenone) can reduce CV morbidity and mortality in HFrEF.[44]

Heart Failure with Preserved Ejection Fraction

Approximately 50% of patients with HF have a preserved ejection fraction (HFpEF). In HFpEF, patients have signs and symptoms of HF such as dyspnea, fatigue, and possibly edema, but they have a preserved left ventricular ejection fraction (≥50%).

Unlike interventions using GDMT in HFrEF, which have been shown to decrease morbidity and mortality in HF, trials using the same antihypertensive medications in HFpEF have not shown similar benefits.[44] Therefore, treatment should be targeted at any underline symptoms, appropriate management of any underlying coronary artery disease, and attainment of goal BP to prevent progression of HF. Patients should use a β-blocker or an ACEi or ARB to treat hypertension, but if signs and symptoms of edema are present, they should receive a diuretic.[1] A mineralocorticoid receptor antagonist may be considered in patients with elevated brain natriuretic peptide concentrations or heart failure admission within one year and adequate kidney function to reduce the risk of hospitalizations.[42]

Stable Ischemic Heart Disease

Chronic stable angina and a history of acute coronary syndrome (unstable angina or acute MI) are forms of stable ischemic heart disease (aka, coronary artery disease, or coronary heart disease).[1] These are the most common forms of hypertension-associated complications. Patients with stable ischemic heart disease are at high risk for a CV event.

β-Blocker therapy has been a standard of care for treating patients with stable ischemic heart disease and hypertension for decades because they can reduce BP and improve angina symptoms by decreasing myocardial oxygen consumption and demand.[1] They also decrease cardiac adrenergic stimulation and have been shown in clinical trials to reduce the risk of a subsequent MI and sudden cardiac death. β-Blocker therapy seems to be most effective in reducing the risk of CV events in patients with recent MI and/or ischemic symptoms. While data indicate that the long-term risk of CV events and mortality may not be reduced with β-blocker therapy in patients with stable coronary artery disease (ie, do not have ischemic symptoms or have a distant history of MI),[45] β-blockers should be used for the treatment of hypertension in patients with stable ischemic heart disease.[1] An ACEi (or ARB as an alternative) has been shown to improve cardiac remodeling and cardiac function and reduce CV events in stable ischemic heart disease as an add-on to a β-blocker.

A long-acting nondihydropyridine CCBs is an alternative to a β-blocker (diltiazem and verapamil) in stable ischemic heart disease.[46] The International Verapamil–Trandolapril Study (INVEST) demonstrated no difference in CV risk reduction when β-blocker-based therapy was compared with nondihydropyridine CCB-based treatment in this population.[47] Nonetheless, the preponderance of data is with β-blockers, and they remain the therapy of choice.[1,46] Importantly, the combined use of a nondihydropyridine CCB with a β-blocker should be avoided in general due to the increased risk of bradycardia.

A dihydropyridine CCB (eg, amlodipine, felodipine) is recommended as add-on therapy in stable ischemic heart disease patients who have ongoing ischemic symptoms (aka, angina or chest pain).[46] CCBs (especially nondihydropyridine CCBs) and β-blockers provide anti-ischemic effects; they lower BP and reduce myocardial oxygen demand in patients with hypertension and stable (and unstable) ischemic heart disease. Moreover, a dihydropyridine CCB can be used in combination with a β-blocker because there is not an increased risk of bradycardia. However, cardiac stimulation may occur with dihydropyridine CCBs (particularly immediate-release formulations) or β-blockers with intrinsic sympathomimetic activity (ISA), making these agents less desirable. Moreover, β-blockers with ISA should be avoided due to these deleterious effects.

Once ischemic symptoms are controlled with β-blocker and/or CCB therapy, other antihypertensive drugs can be added to provide additional CV risk reduction. Clinical trials have demonstrated that the addition of an ACEi further reduces CV events in patients with stable ischemic heart disease.[46] ARBs may provide similar benefits but have not been as extensively studied as ACEi therapy. Therefore, in stable ischemic heart disease, an ARB is generally considered an alternative to an ACEi. Thiazides can be added after that to provide additional BP lowering and to reduce CV risk further. However, thiazides do not provide anti-ischemic effects.

Diabetes Mellitus

The primary cause of mortality in patients with diabetes is CV disease, and hypertension management is an important risk reduction strategy.[1] All four first-line antihypertensive agents (ACEi, ARB, CCB, and thiazides) have been shown to reduce CV events in patients with diabetes (see Fig. 30-3).[1] The evidence-based review performed for the 2017 ACC/AHA guideline found no difference in all-cause mortality, CV mortality, HF, or stroke between ACEi-, ARB-, CCB-, or thiazide-based regimen in patients with diabetes.[17]

Traditionally, an ACEi or ARB was considered as a preferred antihypertensive agent for patients with diabetes. The reasons for this were that pharmacologically, ACEis and ARBs should provide nephroprotection due to vasodilation in the efferent arteriole of the kidney. Evidence from clinical studies has shown reductions in both CV risk (mostly with an ACEi) and reduction in risk of progressive kidney dysfunction (mainly with ARBs) in patients with diabetes.[13,48] However, data indicate that an ACEi or ARB does not confer significantly better CV risk reduction compared to CCBs, thiazides, or β-blockers in patients with diabetes.[48,49] In addition, the risk of kidney disease progression is low in the absence of albuminuria (urine albumin-to-creatinine ratio ≥30 mg/g [3.4 mg/mmol]),[13,48] and many of the studies evaluating the ability of an ACEi or ARB to slow the progression of kidney dysfunction were placebo-controlled.[49] Therefore, an ACEi or ARB are recommended similarly to a CCB or thiazide in patients with diabetes and hypertension that do not have persistent albuminuria.[1]

After first-line antihypertensives (ACEi, ARB, CCB, and thiazide), a β-blocker is useful add-on therapy for BP control for patients with diabetes or to treat another compelling indication (eg, stable ischemic heart disease). A β-blocker (especially nonselective agents) can mask the signs and symptoms of hypoglycemia in patients with tightly controlled diabetes because most of the symptoms of hypoglycemia (eg, tremor, tachycardia, and palpitations) are mediated through the sympathetic nervous system. In addition, sweating, a cholinergically mediated symptom of hypoglycemia, still occurs during a hypoglycemic episode despite β-blocker therapy. Patients may also have a delay in hypoglycemia recovery time because compensatory recovery mechanisms need the catecholamine inputs that are antagonized by β-blocker therapy. Finally, unopposed α-receptor stimulation during the acute hypoglycemic recovery phase (due to endogenous epinephrine release intended to reverse hypoglycemia) may result in acutely elevated BP due to vasoconstriction. Despite these potential concerns, β-blockers can be safely used for patients with diabetes, and are recommended in patients with diabetes that also have a compelling indication (eg, stable ischemic heart disease, HF).

Based on the weight of all evidence, any first-line agent can be used for controlling hypertension for patients with diabetes in the absence of albuminuria. However, regardless of what agent is initially chosen, most patients will require combination therapy (discussed later), typically involving and ACEi or ARB with a CCB or thiazide.

Chronic Kidney Disease

Hypertension, especially uncontrolled BP, can damage the renal tissue (parenchyma) and/or the renal arteries that lead to CKD.[13] CKD in patients with hypertension initially presents as moderately increased albuminuria (urine albumin-to-creatinine ratio 30-299 mg/g [3.4-33.8 mg/mmol] on a spot urine sample or ≥30 mg albumin in a 24-hour urine collection) that can progress to overt kidney failure. The rate of kidney function deterioration is accelerated when both hypertension and diabetes are present. Patients with significant CKD (eg, GFR <60 mL/min/1.73m^2 and/or albuminuria) have an increased risk of CV disease, and further progression to severe CKD.[1] BP control can slow the decline in kidney function and reduce the risk of a CV event in patients with CKD.

In addition to lowering BP, ACEi and ARB therapy can reduce intraglomerular pressure, which can theoretically provide additional benefits by slowing CKD progression in patients with diabetes[48] and those without diabetes.[13] It is difficult to differentiate whether the kidney protection benefits are from RAAS blockade versus BP lowering. A meta-analysis failed to demonstrate any unique long-term kidney protective effects of RAAS-blocking drugs compared with other antihypertensive drugs, suggesting that benefits may be attributed to BP lowering.[50] Moreover, a subgroup analysis of patients from the ALLHAT stratified by different baseline GFR values also did not show a difference in long-term outcomes with chlorthalidone versus lisinopril among patients with significant CKD.[35]

Patients may experience a rapid and profound drop in BP or acute kidney injury when initially starting an ACEi or ARB. The potential to produce acute kidney injury is particularly problematic in patients with significant bilateral renal artery stenosis or a solitary functioning kidney with stenosis. Patients with renal artery stenosis are usually older, and this condition is more common in patients with diabetes or those who smoke. Patients with renal artery stenosis do not always have evidence of kidney disease unless specific tests are performed. Starting with low dosages and evaluating serum creatinine soon after starting either an ACEi or ARB can minimize this risk.

Secondary Stroke Prevention

Ischemic stroke (not hemorrhagic stroke) and TIA are considered hypertension-associated complications. More than two-thirds of patients who have had an ischemic stroke or TIA have hypertension.[1] Achieving goal BP values in patients who have experienced an ischemic stroke is considered a primary modality to reduce the risk of recurrent stroke or TIA. A thiazide, either in combination with an ACEi or as monotherapy, is an evidence-based antihypertensive regimen for patients with a history of stroke or TIA.[1,51,52] ARB-based therapy has also been studied in this population.[53,54] Antihypertensive drug therapy should only be implemented after patients have stabilized following an acute cerebrovascular event, typically a few days after the event.[1] Moreover, the threshold for starting antihypertensive drug therapy in patients with a history of stroke is when BP is above 140/90 mm Hg.[1] Once antihypertensive therapy is initiated, these patients should be treated to a goal of <130/80 mm Hg.

Alternative Drug Treatments

It is sometimes necessary to use other antihypertensive agents such as a mineralocorticoid receptor antagonist, α-blocker, central α_2-agonist, adrenergic inhibitor, or arterial vasodilator. Although these agents effectively lower BP, they either do not have convincing evidence showing reduced morbidity and mortality in hypertension or have a high incidence of adverse effects that significantly hinder tolerability. Alternative agents are generally reserved for patients with resistant hypertension or as add-on therapy with multiple other first-line antihypertensive agents.

Special Populations

Drug therapy selection should always follow the recommendations provided by evidence-based guidelines, summarized in Figs. 30-2 and 30-3.[1] These should be maintained as the guiding principles of drug therapy. However, there are some patient populations where the approach to drug therapy may be slightly altered. In some cases, this is because other agents have unique properties that benefit a coexisting condition but may not be based on evidence from outcome studies in hypertension.

Hypertension in Older People

Hypertension often presents as isolated systolic hypertension in older patients.[1] Epidemiologic data indicate that CV morbidity and mortality are more directly correlated to SBP than to DBP for patients aged 50 years and older. This population is also at high risk for hypertension-associated complications.[1] Although several placebo-controlled trials have specifically demonstrated risk reduction in this population, many older people with hypertension are either not treated or are treated but not at goal BP.

The SHEP was a landmark double-blind, placebo-controlled trial that evaluated chlorthalidone-based treatment for isolated systolic hypertension.[6] A 36% reduction in total stroke, a 27% reduction in coronary artery disease, and 55% reduction in HF were demonstrated versus placebo. The Systolic Hypertension in Europe (Syst-Eur) trial was another placebo-controlled trial that evaluated treatment with a long-acting dihydropyridine CCB.[8] Treatment resulted in a 42% reduction in stroke, 26% reduction in coronary artery disease, and 29% reduction in HF. These data demonstrate reductions in CV morbidity and mortality in older patients with isolated systolic hypertension, especially with thiazides and long-acting dihydropyridine CCBs.

The "very elderly" population (80 years of age and older) were underrepresented in the SHEP and Syst-Eur studies. Historically, this population was often not treated to goal either due to fear of side effects or limited evidence demonstrating benefit. However, the Hypertension in the Very Elderly Trial

(HYVET) provided definitive evidence that antihypertensive drug therapy offers significant clinical benefits in these patients.[55] The HYVET was a prospective controlled clinical trial that randomized patients 80 years and older with hypertension to placebo or antihypertensive drug therapy. It was stopped early after a median of only 1.8 years because the incidence of death was 21% higher in placebo-treated patients. Based on these results, hypertension should be treated with antihypertensive drug therapy in patients age 80 years and older.

Thiazide or β-blocker therapy has been compared with either an ACEi or CCB in older patients with systolic hypertension, diastolic hypertension, or both in the Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study.[56] In this trial, no significant differences in the primary CV event endpoint were seen between the thiazide-based treatment and either an ACEi or CCB. Overall, selecting a treatment that is well-tolerated and affordable may be more important than using specific antihypertensive agents in this population.

Older patients are more sensitive to volume depletion and sympathetic inhibition than younger patients. This may lead to orthostatic hypotension (see the 9.5-4-3 section). In older patients, this can increase the risk of falls due to the associated dizziness. Therefore, centrally acting agents and α_1-blockers should generally be avoided or used with caution in older patients because they are frequently associated with dizziness and orthostatic hypotension. First-line antihypertensives provide significant benefits and can safely be used in older patients, especially those age 80 years and older, but smaller-than-usual initial doses must be used for initial therapy.

The best evidence for lower BP goals in older patients comes from the SPRINT-Senior trial, a prespecified subanalysis of patients aged 75 years and older enrolled in the SPRINT study.[57] In this cohort, older (mean age 79.9 years), community-dwelling patients without dementia and an expected life expectancy of 3 or more years who were treated to an SBP of <120 mm Hg compared an SBP of <140 mm Hg experienced a 34% reduced risk of the primary composite outcome of CVD and 33% reduced risk of all-cause mortality. While the lower SBP goal was associated with an increased risk of hypotension and electrolyte abnormalities, there was no difference in serious adverse events. The benefits of lower BP goals in older patients significantly outweighed the risk, though careful monitoring is essential to ensure safe medication use. A subsequent meta-analysis examining the risks and benefits of lower BP compared to a “relaxed” goal of <150 mm Hg found similar results.[58] Therefore, based on the totality of the evidence, older ambulatory patients should be treated to a SBP goal of <130 mm Hg.[1]

The treatment of hypertension in older patients should follow the same principles outlined for general care of hypertension. However, in patients with multiple comorbidities or disease states, or in whom the benefit of therapy may be less established (eg, nursing home resident, dementia), the risks and benefits of using a lower BP goal should be considered, taking into account patient preference and using a team-based approach. A relaxed SBP goal of <150 mm Hg (<140 mm Hg if tolerated) may be considered appropriate in these patients. Also, while the general approach to treatment is similar to younger patients, initial drug doses may be lower, and dosage titrations over a more extended period are usually needed to minimize the risk of hypotension.

Patients at Risk for Orthostatic Hypotension

⑪ Orthostatic hypotension is a significant drop in BP when standing and can be associated with dizziness and/or fainting. It is defined as an SBP decrease of >20 mm Hg or DBP decrease of >10 mm Hg when changing from supine to standing.[1] The risk of orthostatic hypotension is increased in older patients (especially those with isolated systolic hypotension, or those aged 80 years or older) and those with long-standing diabetes, severe volume depletion, baroreflex dysfunction, autonomic insufficiency, and concomitant use of medications that cause venodilation (α-blockers, mixed α-/β-blockers, nitrates, and phosphodiesterase inhibitors). Interestingly, in a meta-analysis of 18,466 adults enrolled in randomized trials, intensive BP-lowering treatment was associated with a lower risk of orthostatic hypotension, possibly through improvement in long-term maladaptive mechanisms associated with high blood pressure.[59] For patients with risk factors for orthostatic hypotension, antihypertensive agents, especially a thiazide, ACEi, or ARB, should be started in low doses.

Hypertension in Children and Adolescents

Detecting hypertension in children requires customized evaluation. Hypertension is defined as SBP or DBP that is >95th percentile for sex, age, and height on at least three occasions for children.[60] BP values between the 90th and 95th percentile, or >120/80 mm Hg in adolescents, is considered elevated BP. Hypertensive children often have a family history of high BP, and many are overweight or obese, predisposing them to insulin resistance and associated CV risk. Unlike hypertension in adults, secondary hypertension is more common in children and adolescents. Therefore, an appropriate workup for secondary causes is required if elevated BP is identified. Kidney disease (eg, pyelonephritis, glomerulonephritis) is the most common cause of secondary hypertension in children.

Nonpharmacologic treatment (eg, weight loss if overweight or obese, healthy diet, sleep, physical activity) is the cornerstone of therapy for essential hypertension in children.[60] The goal is to reduce the BP to <90th percentile for sex, age, and height and <130/80 mm Hg in adolescents aged 13 years and older.[60] An ACEi, ARB, β-blocker, CCB, and thiazide are all acceptable choices in children and have data supporting their use.[60] If an ACEi or ARB is to be used in adolescent girls of childbearing age, it is important to counsel regarding the risk of fetal injury and death since these agents are teratogenic, and an alternative antihypertensive may be considered. As with adults, the selection of initial agents should be based on the presence of compelling indications or concurrent conditions that may warrant their use.

Pregnancy

Hypertension during pregnancy is a major cause of maternal and neonatal morbidity and mortality.[1] Hypertension during pregnancy can be categorized as preeclampsia, eclampsia, chronic hypertension, preeclampsia superimposed on chronic hypertension, and gestational hypertension.[61] *Preeclampsia* is defined as hypertension (elevated BP ≥140/90 mm Hg on >2 occasions at least 4 hours apart after 20 weeks gestation or ≥160/110 mm Hg confirmed within a short interval) and either proteinuria or new-onset hypertension with the onset of thrombocytopenia, impaired liver function, new-onset renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbances. It can lead to life-threatening complications for both mother and fetus. *Eclampsia*, the onset of convulsions in preeclampsia, is a medical emergency. Chronic hypertension is hypertension that predates pregnancy; superimposed preeclampsia is chronic hypertension associated with preeclampsia. *Gestational hypertension* is defined as new-onset hypertension arising after 20 weeks of gestation in a patient with normal BP before pregnancy that is not in the severe range (≥160/110 mm Hg), without proteinuria or other systemic findings (eg, thrombocytopenia, renal insufficiency, pulmonary edema, cerebral or visual disturbances).

It is controversial whether treating mild-to-moderate hypertension in pregnancy is beneficial. However, women with chronic hypertension before pregnancy are at increased risk of several complications, including superimposed preeclampsia, preterm delivery, fetal growth restriction or demise, placental abruption, HF, and acute kidney failure.[61,62] In an open, international, multicenter study of patients with nonproteinuric preexisting or gestational hypertension, tighter DBP goals (<85 mm Hg) was not associated with decreased rates of the primary composite outcome of pregnancy loss or high-level neonatal care compared to less-tight control (DBP <100 mm Hg).[63] However, severe hypertension (≥160/110 mm Hg) developed less often in patients randomized to the tight control group compared to less-tight control (40.6% vs 27.5%).

The treatment of severe hypertension, pre-eclampsia, and eclampsia is discussed in Chapter e31. For chronic hypertension in pregnancy, several agents may be considered (Table 30-7). Unfortunately, there are few data regarding the most appropriate therapy in pregnancy. Labetalol, long-acting nifedipine, or methyldopa are recommended as first-line agents due to their favorable safety profile.[62] Other β-Blockers (not atenolol) and CCBs are also reasonable alternatives. An ACEi, ARB, and direct renin inhibitor are known teratogens and are absolutely contraindicated.

TABLE 30-7

Treatment of Chronic Hypertension in Pregnancy

Medication/Class	Comments
Methyldopa	Long-term follow-up data supports safety; considered a preferred agent
β-Blockers	Generally safe, but intrauterine growth retardation reported (mostly with atenolol)
Labetalol	Increasingly used over methyldopa because of fewer side effects; considered a first-line agent
Clonidine	Limited data available; mainly an option in the third trimester
CCB	Limited data available; no increase in major teratogenicity with exposure (except immediate-release oral nifedipine should not be used); long-acting nifedipine considered a preferred agent
Thiazide	Not first-line agents but probably safe in low doses if started prior to conception when treating essential hypertension
ACEi, ARB, direct renin inhibitor	Contraindicated; major teratogenicity reported with exposure (fetal toxicity and death)

Black Patients

Hypertension affects Black patients at a disproportionately higher rate, and hypertension-associated complications are more prevalent than in other populations.[1] Reasons for these differences are not fully understood. Hypertension is also more challenging to control in Black patients and usually requires two or more antihypertensives to reach a goal of <130/80 mm Hg.[1]

BP-lowering effects of antihypertensive medication classes vary in Black patients but individual treatment response should always guide therapy, not race. CCBs and thiazides, as monotherapy, are more effective at lowering BP in Black patients and should be used first-line in the absence of a compelling indication.[1] When either of these two classes (especially thiazides) are used in combination with a β-blocker, ACEi, or ARB (which are three classes known to be less effective, on average, at lowering BP in Black patients), the antihypertensive response is increased. This may be due to the low-renin pattern of hypertension in Black patients, resulting in less BP lowering with a β-blocker, ACEi, or ARB when used as monotherapy when compared with other patient populations. Importantly, Black patients have a higher risk of angioedema from an ACEi compared with White patients, though this is not a common adverse effect.[1]

Despite potential differences in antihypertensive effects with monotherapy treatment, drug therapy selection is no different from what is recommended for the hypertensive population in general, and individual treatment response should always guide therapy, not race. Medications recommended for specific compelling indications should be used when such compelling indications are present, even if the antihypertensive effect may not be as great as with another drug class (eg, use a β-blocker first-line for hypertension in a Black patient with stable ischemic heart disease or an ACE or ARB in a Black patient with CKD).

Other Conditions

Most patients with hypertension have other coexisting conditions that may influence the selection of drug therapy. The influence of comorbid conditions should only be complementary to, and never replace, drug therapy choices recommended to treat a compelling indication. Under some circumstances, these considerations help decide on a particular antihypertensive agent when more than one antihypertensive class is recommended. In some cases, an agent should be avoided because it may aggravate a concomitant disorder. In other cases, an antihypertensive can be used to treat hypertension and another concomitant condition. These are briefly summarized in Table 30-5.

Pulmonary Disease and Peripheral Arterial Disease

β-Blockers, especially nonselective agents, have generally been avoided for patients with hypertension and reactive airway disease (asthma or chronic obstructive pulmonary disease [COPD] with a reversible obstructive component) due to a fear of inducing bronchospasm. However, cardioselective β-blockers can safely be used in patients with asthma or COPD.[1] Therefore, cardioselective β-blockers should be used to treat a compelling indication (ie, stable ischemic heart disease or HF) for patients with reactive airway disease.

PAD is a non-coronary form of ASCVD. Patients with PAD are at an increased risk of stroke and CV events.[1,64] While β-blockers can theoretically be problematic for patients with PAD due to possible decreased peripheral blood flow secondary to unopposed stimulation of α_1-receptors that results in vasoconstriction, available data indicate that β-blockers do not worsen claudication symptoms or cause functional impairment.[64] Antihypertensive treatment for patients with PAD should follow the same general principles as patients without PAD.[1]

Metabolic Syndrome

Metabolic syndrome is a cluster of multiple cardiometabolic risk factors.[1] It has been defined as the presence of three of the following five criteria: abdominal obesity, elevated triglycerides, low HDL cholesterol, elevated BP (or receiving drug treatment for high BP), and elevated fasting blood glucose.[65] It is widely accepted that patients with metabolic syndrome are at increased risk of developing CV disease and/or type 2 diabetes. The cornerstone of treatment involves lifestyle modification (eg, weight loss if overweight or obese, exercise, dietary modifications). There is no definitive evidence that any first-line antihypertensive medication class is better or worse than another in reducing CV events in patients with metabolic syndrome.[1] While thiazides have been associated with a slight increase in blood glucose and faster progression to diabetes, a subgroup analysis of ALLHAT found that CV events were reduced more with chlorthalidone when compared to lisinopril in patients with impaired fasting glucose.[36] Therefore, any first-line antihypertensive can be used for patients with metabolic syndrome.

Erectile Dysfunction

Most antihypertensive agents, particularly β-blockers and mineralocorticoid receptor antagonists, have been associated with erectile dysfunction in men. However, it is not clear if erectile dysfunction associated with antihypertensive treatment is solely a result of drug therapy or rather a symptom of underlying vascular disease. β-Blockers have historically been labeled as agents that cause significant sexual dysfunction. However, evidence supporting this notion is limited. A systematic review of 15 studies involving 35,000 patients assessing β-blocker use for MI, HF, and hypertension found only a slight increased risk for erectile dysfunction.[66] In addition, prospective long-term data from the Treatment of Mild Hypertension Study (TOMHS) and the Veterans Administration Cooperative trial show no difference in the incidence of erectile dysfunction between thiazide and β-blocker versus an ACEi and CCB.[67,68] Centrally acting agents are associated with higher rates of sexual dysfunction and should be avoided in men with erectile dysfunction.

Hypertensive men frequently have ASCVD, which frequently results in erectile dysfunction. Therefore, erectile dysfunction is associated with chronic arterial changes resulting from elevated BP, and lack of control may increase the risk of erectile dysfunction. These changes are even more pronounced in hypertensive men with diabetes.

Resistant Hypertension

⑫ Resistant hypertension is defined as failure to achieve goal BP using three or more antihypertensive drugs with complementary mechanisms of action (ideally using optimal doses, one of which is a diuretic) or when four or more antihypertensive drugs are needed to achieve BP control.[1,69] Approximately 12% to 15% of patients with hypertension have apparent treatment-resistant hypertension.[69] Patients with newly diagnosed hypertension or who are not receiving drug therapy should not be considered to have resistant hypertension. Difficult-to-control hypertension is persistently elevated BP despite treatment with two or three drugs, which fails to meet the criteria for resistant hypertension.

Several causes of resistant hypertension are listed in Table 30-8. Volume overload is a common cause, thus highlighting the importance of diuretic therapy in managing hypertension. Pseudoresistance should also be ruled out by assuring adherence to prescribed therapy and possibly using home BP measurements (using a self-monitoring device or 24-hour ABP monitor).[1] Patients should be closely evaluated to see if any of these causes can be reversed.

TABLE 30-8

Causes of Resistant Hypertension

Improper BP measurement

Volume overload:

- Excess sodium intake
- Volume retention from kidney disease
- Inadequate diuretic therapy

Drug-induced or other causes:

- Nonadherence
- Inadequate doses
- Agents listed in Table 30-1

Associated conditions:

- Obesity
- Excess alcohol intake
- Obstructive sleep apnea

Secondary hypertension

Treatment of patients with resistant hypertension should ultimately follow the principle of drug therapy selection from the 2017 ACC/AHA guideline. Compelling indications, if present, should guide selection assuming that these patients are on a thiazide or other type of diuretic. However, there are treatment philosophies that are germane to the management of resistant hypertension: (a) assuring adequate diuretic therapy, (b) appropriate use of combination therapy, and (c) using alternative antihypertensive agents when needed.

Assuring Appropriate Diuretic Therapy

Diuretics have a prominent role in the pharmacotherapy of resistant hypertension. Thiazides are first-line antihypertensive agents, but chlorthalidone (thiazide-like) is recommended ahead of hydrochlorothiazide for patients with resistant hypertension because it is more potent on a milligram-per-milligram basis.[69] Though less commonly used, indapamide (similar to chlorthalidone as “thiazide-like”) is also a more potent antihypertensive agent than hydrochlorothiazide at commonly prescribed doses, and the evidence does not demonstrate a higher risk of metabolic side effects.[70]

A mineralocorticoid receptor antagonist (eg, spironolactone) is a highly effective add-on agent.[1,69] Data indicate that many patients with resistant hypertension have some degree of underlying hyperaldosteronism, justifying the role of adding a mineralocorticoid receptor antagonist. Spironolactone has been compared to an α-blocker and a β-blocker as add-on therapy for resistant hypertension in the PATHWAY-2 study.[71] The BP-lowering effect of spironolactone was approximately double that of doxazosin and bisoprolol, reinforcing the benefits of blocking aldosterone by using a mineralocorticoid receptor antagonist in managing resistant hypertension.

Clinicians may consider using a loop diuretic, even in place of a thiazide, for patients with resistant hypertension who have compromised kidney function (eg, estimated GFR <15 mL/min/1.73m^2).[1,69] When a loop diuretic is used, a long-acting agent such as torsemide, which can be dosed once daily, should be used over shorter-acting agents such as furosemide and bumetanide, which may need to be dosed multiple times a day.[69]

First-Line Antihypertensive Agents

Angiotensin-Converting Enzyme Inhibitors (ACEi)

An ACEi is a first-line therapy option in most patients with hypertension.[1] The ALLHAT demonstrated less HF and stroke with chlorthalidone versus lisinopril,[26] while another outcome study showed similar, if not better, outcomes with an ACEi versus hydrochlorothiazide.[32] It is possible that the different thiazides have different abilities to reduce CV events. Nonetheless, strong evidence demonstrates that ACEi therapy overall reduces CV events comparably to other first-line antihypertensive agents.

ACE facilitates the production of angiotensin II that has a major role in arterial BP regulation, as depicted in Fig. 30-1. ACE is distributed in many tissues and is present in several different cell types, but its main location is endothelial cells. Therefore, the primary site for angiotensin II production is in the blood vessels, not the kidney. An ACEi blocks the ACE, thus inhibiting the conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor that stimulates aldosterone secretion, causing an increase in sodium and water reabsorption with accompanying potassium loss. By blocking the ACE, vasodilation and a decrease in aldosterone occur.

An ACEi also blocks the degradation of bradykinin and stimulates the synthesis of other vasodilating substances (prostaglandin E_2 and prostacyclin). Because an ACEi lowers BP in patients with normal plasma renin activity, bradykinin and perhaps tissue production of ACE are important in hypertension. Increased bradykinin enhances the BP-lowering effects of an ACEi, and is also responsible for the side effect of a dry cough. An ACEi may effectively prevent or regress LVH by reducing direct stimulation of angiotensin II on myocardial cells.

There are many evidence-based indications for an ACEi (see Fig. 30-3). An ACEi reduces CV morbidity and mortality in patients with HFrEF and decreases the progression of CKD. An ACEi is a first-line option for patients with diabetes and hypertension because of demonstrated CV disease and kidney benefits. A two-drug regimen of an ACEi with a thiazide is first-line in recurrent stroke prevention based on benefits demonstrated from the PROGRESS trial showing a reduced risk of secondary stroke.[31] As an add-on to β-blocker therapy, evidence indicates that an ACEi further reduces CV risk in patients with stable ischemic heart disease.[46,72–74]

Most ACEi medications can be dosed once daily for hypertension (Table 30-5). In some patients, especially when higher doses are used, twice-daily dosing is needed to maintain 24-hour effects with enalapril, benazepril, moexipril, quinapril, and ramipril.

ACEi therapy is generally well tolerated. Because they decrease aldosterone, an increase in potassium serum concentrations can occur. While this increase is usually small, hyperkalemia is possible. Patients with CKD or taking other agents which may increase potassium (eg, potassium supplements, potassium-sparing diuretics, mineralocorticoid receptor antagonists) are at the highest risk for hyperkalemia. Judicious monitoring of serum potassium and creatinine values within 4 weeks of starting or increasing the dose of an ACEi can often identify abnormalities early before they evolve into serious adverse events.

The most worrisome adverse effect of ACEi therapy is acute kidney injury. This serious adverse effect is uncommon, and the development of severe acute kidney failure is rare, occurring in less than 1% of patients. Preexisting kidney disease increases the risk of this side effect. Severe bilateral renal artery stenosis or unilateral stenosis of a solitary functioning kidney renders patients dependent on the vasoconstrictive effect of angiotensin II on the efferent arteriole of the kidney, thus explaining why these patients are particularly susceptible to acute kidney injury from an ACEi. Slow titration of the ACEi dose and judicious kidney function monitoring can minimize risk and allow early detection of patients with renal artery stenosis.

GFR does decrease somewhat in patients when started on an ACEi.[1] This is attributed to the inhibition of angiotensin II vasoconstriction on the efferent arteriole. This decrease in GFR often increases serum creatinine, and small increases should be anticipated when monitoring patients newly started on an ACEi. Either modest elevations of ≤35% (for baseline creatinine values ≤3 mg/dL [265 μmol/L]) or absolute increases <1 mg/dL (88 μmol/L) do not warrant changes. If larger increases occur, ACEi therapy should be stopped or the dose reduced.

Angioedema is a serious potential complication of ACEi therapy. It occurs in <1% of the population and is more likely in Black patients and smokers. Symptoms include lip and tongue swelling and possibly difficulty breathing. All patients with ACEi-induced angioedema should have ACEi therapy stopped. However, angioedema associated with laryngeal edema and/or pulmonary symptoms occasionally occurs and requires additional treatment with a bradykinin B2 receptor antagonist (eg, icatibant), fresh frozen plasma, and/or emergent intubations to support respiration. Even if not from an ACEi, a history of angioedema precludes the use of an ACEi (it is a contraindication). Cross-reactivity between an ACEi and an ARB does not appear to be a significant concern. The Telmisartan Randomized Assessment Study in ACE-Intolerant Subjects with Cardiovascular Disease (TRANSCEND) trial enrolled 75 patients with a history of ACEi–induced angioedema and randomized these patients to either placebo or ARB therapy.[75] There were no cases of repeat angioedema among these patients. These data suggest that the cross-reactivity is low. Hence, an ARB can be used in a patient with a history of ACEi–induced angioedema when needed. However, clinicians should monitor for repeat occurrences since idiopathic angioedema may still occur.

A persistent dry cough may develop in up to 20% of patients treated with an ACEi. The inhibition of bradykinin breakdown pharmacologically explains it. This cough does not cause pulmonary disease but is annoying and can compromise adherence. It should be differentiated from a "wet" cough due to pulmonary edema, which may be a sign of uncontrolled HF and not an ACEi-induced cough.

An ACEi (and ARB or direct renin inhibitor) is absolutely contraindicated in pregnancy. Female patients of childbearing age should be counseled regarding effective birth control as ACEi therapy are fetotoxic.[1] Fetopathy (group of conditions that includes renal failure, renal dysplasia, hypotension, oligohydramnios, pulmonary hypotension, hypocalvaria, and death) has occurred with ACEi exposure in the second and third trimesters. Similar to a thiazide, an ACEi can increase lithium serum concentrations in patients on lithium therapy. Concurrent use of an ACEi with a potassium-sparing diuretic, potassium supplements, or mineralocorticoid receptor antagonist may result in hyperkalemia. An ACEi should not be used with an ARB or direct renin inhibitor to avoid possible hyperkalemia.

Lower than normal starting doses of an ACEi should be used for patients at risk for orthostatic hypotension or severe renal dysfunction (eg, elderly patients, those with CKD). Acute hypotension may occur at the onset of ACEi therapy. Patients who are sodium or volume-depleted, in an HF exacerbation, very elderly, or on concurrent vasodilators or thiazide therapy are at high risk for this effect. It is important to start with half the usual dose of an ACEi for all patients with these risk factors and use slow dose titration.

Angiotensin Receptor Blockers (ARBs)

Two enzymatic pathways generate Angiotensin II: the RAAS, which involves ACE, and an alternative path that uses other enzymes such as chymase (aka "tissue ACE"). An ACEi inhibits only the effects of angiotensin II produced through the RAAS, whereas ARBs inhibit angiotensin II from all pathways. It is unclear how these differences affect tissue concentrations of ACE.

ARB therapy directly blocks the AT_1 receptor, which mediates the known effects of angiotensin II in humans: vasoconstriction, aldosterone release, sympathetic activation, antidiuretic hormone release, and constriction of the efferent arterioles of the glomerulus. They do not block the AT_2 receptor. Therefore, the beneficial effects of AT_2 receptor stimulation (vasodilation, tissue repair, and inhibition of cell growth) remain intact with ARB use. Unlike an ACEi, an ARB does not block the breakdown of bradykinin. Therefore, some of the beneficial effects of bradykinin (eg, vasodilation) are not present with ARB therapy.

An ARB is a first-line therapy option in most patients with hypertension.[1] ARB therapy has been directly compared with ACEi therapy in patients with high CV risk.[76] The Ongoing Telmisartan Alone and in Combination with Ramipril Global End Point Trial (ON-TARGET) was a double-blind trial that randomized 25,620 patients (69% with a history of hypertension-based historical standards, mean BP of 142/82 mm Hg) to ACEi-based therapy, ARB-based therapy, or the combination of an ACEi with an ARB. After a median follow-up of 56 months, there was no difference in the primary endpoint (CV death or hospitalization for HF) between any of the three treatment groups. Therefore, these data establish that the CV event–lowering benefits of ARB therapy is similar to ACEi therapy. Moreover, the combination of an ACEi with an ARB had no additional benefits on CV events and was associated with a higher risk of side effects (renal dysfunction, hypotension, hyperkalemia). Therefore, concurrent use of an ACEi with an ARB for the management of hypertension is not recommended.[1]

For patients with type 2 diabetes and CKD, the progression of kidney disease is significantly reduced with ARB therapy.[48] Some benefits are independent of BP lowering, suggesting that the pharmacologic effects of ARBs on the efferent arteriole may result in attenuated progression of kidney disease. For patients with HFrEF, ARB therapy has been shown to reduce the risk of hospitalization for HF when used as an alternative therapy in ACEi-intolerant patients.[44]

ARBs have been compared head-to-head with CCBs. The Morbidity and Mortality After Stroke: Eprosartan Versus Nitrendipine in Secondary Prevention (MOSES) trial demonstrated that eprosartan reduced the risk of recurrent stroke greater than nitrendipine in patients with a past medical history of cerebrovascular disease.[53] These data support the common notion that ARBs may have cerebroprotective effects that may explain CV event reductions. Another outcome study, the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) trial, showed that valsartan-based therapy is equivalent to amlodipine-based therapy for the primary composite outcome of first CV event in patients with hypertension and additional CV risk factors.[30] However, the occurrence of certain components of the primary endpoint (stroke and MI) was lower in the valsartan group. Although patients treated with amlodipine had slightly lower mean BP values than valsartan-treated patients, there was no difference in the primary endpoint.

The addition of a CCB or thiazide to an ARB significantly increases antihypertensive efficacy. Similar to an ACEi, most ARBs have long enough half-lives to allow for once-daily dosing. However, candesartan, eprosartan, losartan, and valsartan have the shortest half-lives and may require twice-daily dosing for sustained BP lowering.

ARB therapy has the lowest incidence of side effects compared with other antihypertensive agents.[77] ARBs do not affect bradykinin and do not elicit a dry cough like an ACEi. While referred to as an "ACEi without a cough," pharmacologic differences between an ARB and ACEi highlight that they could have different effects on vascular smooth muscle and myocardial tissue that can correlate to different effects. Regardless, they are first-line options for hypertension, and they are reasonable alternatives for patients who do not tolerate ACEi therapy because of a cough. Due to their excellent tolerability, safety profile, and generic availability, ARBs are increasingly preferred by clinicians over an ACEi for hypertension.

An ARB may cause renal insufficiency, hyperkalemia, and orthostatic hypotension in a manner identical to that of an ACEi. The same precautions that apply to ACEi therapy regarding suspected bilateral renal artery stenosis, concomitant medications that can raise potassium, and/or increase the risk of hypotension apply to ARBs. As previously discussed, patients with a history of ACEi angioedema can be treated with an ARB when needed.[78] An ARB should never be used in pregnancy. An ARB should not be used with an ACEi or direct renin inhibitor.

Calcium Channel Blockers (CCB)

Both dihydropyridine CCBs and nondihydropyridine CCBs are first-line therapies for hypertension.[1] CCBs also have compelling indications in stable ischemic heart disease as an add-on to a β-blocker, while a nondihydropyridine CCBs should be used as an alternative to a β-blocker. However, they are primarily used as add-on therapy to other antihypertensive drug classes with this compelling indication.

Contraction of cardiac and smooth muscle cells requires increased free intracellular calcium concentrations from the extracellular fluid. When the cardiac or vascular smooth muscle is stimulated, voltage-sensitive channels in the cell membrane are opened, allowing calcium to enter the cells. The influx of extracellular calcium into the cell releases stored calcium from the sarcoplasmic reticulum. As intracellular free calcium concentration increases, it binds to a protein, calmodulin, which then activates myosin kinase enabling myosin to interact with actin to induce contraction. CCBs work by inhibiting the influx of calcium across the cell membrane. There are two types of voltage-gated calcium channels: a high-voltage channel (L-type) and a low-voltage channel (T-type). Available CCBs only block the L-type channel, which leads to coronary and peripheral vasodilation.

The two subclasses, dihydropyridines and nondihydropyridines (see Table 30-5), are pharmacologically different from each other. While their antihypertensive effectiveness is similar, they differ somewhat in other pharmacodynamic effects. Nondihydropyridines (verapamil and diltiazem) decrease heart rate and slow atrioventricular nodal conduction. Similar to a β-blocker, these drugs may also treat supraventricular tachyarrhythmias (eg, atrial fibrillation). Verapamil (and diltiazem to a lesser extent) produces negative inotropic and chronotropic effects that are responsible for its propensity to precipitate or cause systolic HF in high-risk patients. All CCBs (except amlodipine and felodipine) have negative inotropic effects. Dihydropyridines may cause a baroreceptor-mediated reflex tachycardia because of their potent peripheral vasodilating effects. This effect is more pronounced with the first-generation dihydropyridines (eg, nifedipine) and is significantly diminished with the newer agents (eg, amlodipine) and when given in sustained-release dosage forms. Dihydropyridines do not alter conduction through the atrioventricular node and thus are not effective agents in supraventricular tachyarrhythmias.

Dihydropyridine CCBs have been extensively studied in hypertension and are the primary agents used for this indication. In ALLHAT, there was no difference in the primary outcome between chlorthalidone and amlodipine, and only the secondary outcome of HF was higher with amlodipine.[26] A subgroup analysis of ALLHAT directly compared amlodipine with lisinopril and demonstrated that there was no difference in the primary outcome.[79] However, amlodipine was superior to lisinopril for BP control in Black patients, and for stroke reduction in Black patients and women. As discussed previously, the VALUE study also showed no difference between valsartan and amlodipine in the primary outcome of the first CV event in high-risk patients.[30]

Dihydropyridine CCBs are effective in older patients with isolated systolic hypertension. The placebo-controlled Syst-Eur trial demonstrated that a long-acting dihydropyridine CCB reduced the risk of CV events markedly in isolated systolic hypertension.[8] A long-acting dihydropyridine CCB, similar to a thiazide, should be strongly considered as preferred therapy in a patient with isolated systolic hypertension and no other compelling indications.

Among dihydropyridine CCBs, short-acting nifedipine may rarely cause an increase in the frequency, intensity, and duration of angina in association with acute hypotension. This effect is most likely due to reflex sympathetic stimulation and is likely avoided by using sustained-release formulations of nifedipine. For this reason, all other dihydropyridines have an intrinsically long half-life or are sustained-release formulations. Immediate-release nifedipine has been associated with an increased incidence of adverse CV effects, is not approved for the treatment of hypertension, and should never be used to treat hypertension. Other side effects of dihydropyridine CCBs include dizziness, flushing, headache, gingival hyperplasia, peripheral edema, mood changes, and various GI complaints. Side effects due to vasodilation such as dizziness, flushing, headache, and peripheral edema occur more frequently with all dihydropyridine CCBs than with the nondihydropyridine CCBs because they are less potent vasodilators.

Diltiazem and verapamil are nondihydropyridine CCBs that can cause cardiac conduction abnormalities such as bradycardia or atrioventricular block. These problems occur mainly with high doses or when used for patients with preexisting cardiac conduction abnormalities. HF has been reported in otherwise healthy patients due to negative inotropic effects. Both drugs can cause peripheral edema and hypotension. Verapamil causes constipation in some patients. This side effect also occurs with diltiazem, but to a lesser extent.

Verapamil and diltiazem are moderate cytochrome P450 3A4 isoenzyme system inhibitors and can cause drug-drug interactions that result in increased serum concentrations of other drugs metabolized by this isoenzyme system (eg, cyclosporine, digoxin, lovastatin, simvastatin, tacrolimus, theophylline). The use of verapamil or diltiazem with a β-blocker should be avoided for the treatment of hypertension because there is an increased risk of heart block with these combinations. When a CCB is needed in combination with a β-blocker for BP lowering, a dihydropyridine should be selected because it will not increase the risk of heart block. The hepatic metabolism of CCBs, especially felodipine, nicardipine, nifedipine, and nisoldipine, may be inhibited by ingesting large quantities of grapefruit juice (eg, ≥1 quart daily).

Many different formulations of verapamil and diltiazem are currently available (see Table 30-5). Although certain individual sustained-release verapamil and diltiazem products contain the same active drug, they are usually not AB-rated by the FDA as interchangeable on a milligram-per-milligram basis due to different biopharmaceutical release mechanisms. However, the clinical significance of these differences is likely negligible.

Thiazides and Other Diuretics

There are four subclasses of diuretics: thiazides, loops, potassium-sparing agents, and mineralocorticoid receptor antagonists (see Table 30-5).[1,80] A thiazide is the preferred diuretic for hypertension and is considered a first-line therapy option in most patients.[1] The best available evidence justifying this recommendation is from the ALLHAT.[26] Moreover, when combination therapy is needed in hypertension to control BP, a thiazide as an add-on agent, but not necessarily the second agent, is effective in augmenting BP lowering.

Loop diuretics are more potent agents for inducing diuresis but are not ideal antihypertensives unless treating edema is also needed. In general, loop diuretics are sometimes required over a thiazide for hypertension in patients with severe CKD when estimated GFR is <30 mL/min/1.73m^2, especially in the case of hydrochlorothiazide or when edema is present.[69] However, many patients with an estimated GFR between 25 and 30 mL/min/1.73m^2, but not on dialysis, will still have antihypertensive effects with thiazides. This is especially true with chlorthalidone.[69]

Potassium-sparing diuretics are weak antihypertensive agents when used alone and do not enhance antihypertensive effects when combined with a thiazide or loop diuretic. Their use in hypertension is in combination with another diuretic to counteract the potassium-wasting properties of the other diuretic agent.

Mineralocorticoid receptor antagonists (MRAs; spironolactone and eplerenone) inhibit aldosterone activity and are sometimes considered potassium-sparing diuretics. However, they are more potent as antihypertensives and should be viewed as an independent class due to evidence supporting different compelling indications. Mineralocorticoid receptor antagonists are most commonly used to treat resistant hypertension, as elevated aldosterone concentrations are prevalent in this setting. They are also used as an add-on agent in patients with HF, with or without concomitant hypertension.

The exact antihypertensive mechanism of action of non-MRA diuretics is not completely known but has been well hypothesized. The drop in BP seen when they are first started is caused by an initial diuresis. Diuresis causes reductions in plasma and stroke volume, which decreases CO and BP. This initial drop in CO causes a compensatory increase in PVR. With chronic diuretic therapy, extracellular fluid and plasma volume return to near pretreatment values. However, PVR decreases to values that are lower than the pretreatment baseline. This reduction in PVR is responsible for persistent antihypertensive effects.

With thiazides, additional actions may further explain their antihypertensive effects. They mobilize sodium and water from arteriolar walls. This effect would lessen the amount of physical encroachment on the lumen of the vessel created by the excessive accumulation of intracellular fluid. As the diameter of the lumen relaxes and increases, there is less resistance to the flow of blood, and PVR further drops. High dietary sodium intake can blunt this effect, and a low salt intake can enhance this effect. Thiazides are also postulated to cause direct relaxation of vascular smooth muscle.

Diuretics should be dosed in the morning when given once daily and in the morning and late afternoon when dosed twice daily to minimize nocturnal diuresis. However, with chronic use, thiazides, potassium-sparing diuretics, and MRAs rarely cause a pronounced diuresis.

The major pharmacokinetic differences between the different thiazide medications are serum half-life and duration of diuretic effect. The clinical relevance of these differences is unknown because the serum half-life of most antihypertensive agents does not correlate with the hypotensive duration of action. Moreover, diuretics lower BP primarily through extrarenal mechanisms. Hydrochlorothiazide, and to a greater extent chlorthalidone, are the two most frequently used thiazides in landmark clinical trials that have demonstrated reduced morbidity and mortality. Hydrochlorothiazide is considered a “thiazide-type” agent, while chlorthalidone is a “thiazide-like” agent. These agents are not equipotent on a milligram-per-milligram basis; chlorthalidone is 1.5 to 2 times more potent than hydrochlorothiazide.[80] This is likely attributed to a longer half-life (45-60 hours vs 8-15 hours) and a longer duration of effect (48-72 hours vs 16-24 hours) with chlorthalidone.

Thiazides are effective in lowering BP, especially when used in combination with most other antihypertensives. Two independent pharmacodynamic effects explain this additive response. First, when two drugs cause the same overall pharmacologic effect (BP lowering) through different mechanisms of action, their combination usually results in an additive or synergistic effect. This is especially relevant when a β-blocker, ACEi, or ARB is indicated in a Black patient but does not elicit sufficient antihypertensive effect. Adding a thiazide, similar to a CCB, in this situation can often significantly lower BP. Second, a compensatory increase in sodium and fluid retention may be seen with antihypertensive agents. This problem is counteracted with the concurrent use of a thiazide.

Side effects of a thiazide include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, hyperglycemia, dyslipidemia, and sexual dysfunction. Many of these side effects were identified when high doses of thiazides were used in the past (eg, hydrochlorothiazide up to 200 mg/day). Current guidelines recommend dosing hydrochlorothiazide up to 50 mg/day or chlorthalidone up to 25 mg/day, which markedly reduces the risk for most metabolic side effects. Loop diuretics may cause the same side effects. Although the effect on serum lipids and glucose is even less significant, hypokalemia is more pronounced, and hypocalcemia may occur.

Hypokalemia and hypomagnesemia may cause muscle fatigue or cramps. However, serious cardiac arrhythmias can occur in patients with severe hypokalemia and hypomagnesemia. Low-dose therapy (ie, 25 mg hydrochlorothiazide or 12.5 mg chlorthalidone daily) causes less electrolyte disturbances than higher doses. However, because the most effective doses of these two thiazides are hydrochlorothiazide 50 mg daily and chlorthalidone 25 mg daily, efforts should be made to keep potassium in the therapeutic range by careful monitoring, especially when higher doses are used.

Thiazide-induced hyperuricemia can precipitate gout. This side effect may be especially problematic for patients with a previous history of gout and is more common with thiazides. However, acute gout is unlikely in patients with no prior history of gout. If gout occurs in a patient who requires thiazide therapy, allopurinol can be given to prevent gout and not compromise thiazide’s antihypertensive effects. High doses of thiazide and loop diuretics may increase fasting glucose and serum cholesterol values. These effects, however, usually are transient and often inconsequential.[80]

Potassium-sparing diuretics can cause hyperkalemia, especially in patients with CKD or diabetes and in patients receiving concurrent treatment with an MRA, ACEi, ARB, direct renin inhibitor, or potassium supplements. Hyperkalemia is especially problematic for the MRA eplerenone, a selective antagonist of aldosterone. Due to this increased risk of hyperkalemia, eplerenone is contraindicated for patients with impaired kidney function or type 2 diabetes with proteinuria (see Table 30-5). While spironolactone may cause gynecomastia in up to 10% of patients, this rarely occurs with eplerenone.

A thiazide can be used safely with most other agents. However, concurrent administration with lithium may increase lithium serum concentrations and predispose patients to lithium toxicity.

β-Blockers

β-blockers have been used in several large outcome trials in hypertension. However, in most of these trials, a thiazide was the first-line agent with a β-blocker added for additional BP lowering. For patients with hypertension but without compelling indications, a β-blocker should not be used as the initial first-line agent. This recommendation is based on meta-analyses that suggest β-blocker-based therapy may not reduce CV events as well as these other agents when used as the initial drug to treat patients with hypertension who do not have a compelling indication for a β-blocker.[1]

A β-blocker is only an appropriate first-line agent in hypertension when treating specific, compelling indications (eg, stable ischemic heart disease, HF). Numerous trials have shown a reduced risk of CV events when β-blockers are used following an MI, during an acute coronary syndrome, or in patients with chronic stable angina with ischemic symptoms. Although once contraindicated in HF, studies have shown that bisoprolol, carvedilol, and metoprolol succinate reduce mortality in patients with HFrEF who are treated with a diuretic and ACEi.

Several mechanisms of action have been proposed for β-blockers, but none alone has been consistently associated with reducing arterial BP. β-Blocker therapy has negative chronotropic and inotropic effects that reduce CO, which explains some of the antihypertensive effects. However, CO falls equally for patients treated with a β-blocker regardless of BP lowering. Additionally, β-blockers with ISA do not reduce CO, yet they lower BP and decrease peripheral resistance. However, β-blockers with ISA are contraindicated in stable ischemic heart disease because they stimulate β-receptors.

β-Adrenoceptors are also located on the surface membranes of juxtaglomerular cells, and a β-blocker inhibits these receptors and thus the release of renin. However, there is a weak association between plasma renin and the antihypertensive efficacy of β-blocker therapy. Some patients with low plasma renin concentrations do respond to β-blocker treatment. Therefore, additional mechanisms likely also account for the antihypertensive effect of a β-blocker.

There are important pharmacodynamic and pharmacokinetic differences among β-blockers, but all agents provide a similar degree of BP lowering. There are three pharmacodynamic properties of β-blocker therapy that differentiate this class: cardioselectivity, ISA, and membrane-stabilizing effects. β-Blocker agents that possess a greater affinity for β_1-receptors than for β_2-receptors are *cardioselective*.

β_1-Adrenoceptors and β_2-adrenoceptors are distributed throughout the body, but they concentrate differently in specific organs and tissues. There is a preponderance of β_1-receptors in the heart and kidney and a preponderance of β_2-receptors in the lungs, liver, pancreas, and arteriolar smooth muscle. β_1-Receptor stimulation increases heart rate, contractility, and renin release. β_2-Receptor stimulation results in bronchodilation and vasodilation. A cardioselective β-blocker is not likely to provoke bronchospasm and vasoconstriction. β_2-Receptors mediate insulin secretion and glycogenolysis. Blocking β_2-receptors may reduce these processes and increase blood glucose or blunt recovery from hypoglycemia.

Cardioselective β-blockers (eg, bisoprolol, metoprolol, nebivolol) have clinically significant advantages over nonselective agents (eg, propranolol, nadolol) and are preferred when using a β-blocker to treat hypertension. Cardioselective agents are safer than nonselective agents for patients with asthma or diabetes who have a compelling indication for a β-blocker. However, cardioselectivity is a dose-dependent phenomenon; at higher doses, some cardioselective agents lose their relative selectivity for β_1-receptors and block β_2-receptors as effectively as they block β_1-receptors. The dose at which cardioselectivity is lost varies from patient to patient and may not occur with highly selective β-blockers (eg, bisoprolol).

Some β-blockers (eg, acebutolol, pindolol) have ISA and act as partial β-receptor agonists. When they bind to the *β*-receptor, they stimulate it, but far less than a pure β-agonist. If the sympathetic tone is low, as it is during resting states, β-receptors are partially stimulated by ISA β-blockers. Therefore, resting heart rate, CO, and peripheral blood flow are not reduced when these types of β-blockers are used. Theoretically, ISA agents have advantages over non-ISA β-blockers in certain patients with HF or sinus bradycardia. Unfortunately, they do not reduce CV events as well as other β-blockers. In fact, they may increase CV risk in patients with stable ischemic heart disease. Thus, agents with ISA are rarely needed and have no role in the management of hypertension.

Pharmacokinetic differences among β-blockers relate to first-pass metabolism, route of elimination, the degree of lipophilicity, and serum half-lives. Propranolol and metoprolol undergo extensive first-pass metabolism, so the dose needed to attain β-blockade with either drug varies from patient to patient. Atenolol and nadolol are renally excreted. The dose of these agents may need to be reduced for patients with moderate-to-severe CKD.

β-Blockers, especially those with high lipophilic properties, penetrate the central nervous system and may cause other effects. Propranolol is the most lipophilic. It is thought that higher lipophilicity is associated with more central nervous system side effects (dizziness, drowsiness). However, the lipophilic properties provide better effects for non-CV conditions such as migraine headache prevention, essential tremor, and thyrotoxicosis. BP lowering is equal among β-blockers regardless of lipophilicity.

Most side effects of β-blockers are extensions of their ability to antagonize β-adrenoceptors. β-Blockade in the myocardium can be associated with bradycardia, atrioventricular conduction abnormalities (eg, second- or third-degree heart block), and the development of acute HF. The decrease in heart rate may benefit certain patients with atrial arrhythmias (atrial fibrillation, atrial flutter) and hypertension by both providing rate control and BP lowering. β-Blocker therapy usually only produces HF if used in high initial doses for patients with preexisting left ventricular dysfunction or if started in these patients during an acute HF exacerbation. Blocking β_2-receptors in arteriolar smooth muscle may cause cold extremities and may aggravate intermittent claudication or Raynaud's phenomenon due to decreased peripheral blood flow. Also, there is an increase of sympathetic tone during periods of hypoglycemia in patients with diabetes that may result in a significant increase in BP because of unopposed α-receptor-mediated vasoconstriction.

Abrupt cessation of β-blocker therapy can cause harm. Abrupt cessation may lead to rebound hypertension (a sudden increase in BP to or above pretreatment values). Cardiac ischemia (aka, angina, or chest pain), a CV event, or even death in patients with coronary artery disease can also result from abrupt cessation. To avoid this, β-blockers should always be tapered gradually over 1 to 2 weeks before eventually discontinuing the drug. This acute withdrawal syndrome is believed to be secondary to the progression of underlying coronary disease, hypersensitivity of β-adrenergic receptors due to upregulation, and increased physical activity after withdrawal of a drug that decreases myocardial oxygen requirements. For patients without coronary disease, abrupt discontinuation may present as tachycardia, sweating, and generalized malaise in addition to increased BP.

Like a thiazide, β-blocker therapy has been shown to increase serum cholesterol and glucose values, but these effects are transient and of little-to-no clinical significance. For patients with diabetes, the reduction in CV events was as great with β-blocker therapy as with an ACEi in the United Kingdom Prospective Diabetes Study (UKPDS)[81] and far superior to placebo in the SHEP trial.[6] In the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial, patients with diabetes and hypertension who were randomized to metoprolol tartrate had a small increase in hemoglobin A1C values, while patients randomized to carvedilol did not.[82] This suggests that mixed α- and β-blocking effects of carvedilol may be preferential to metoprolol for patients with uncontrolled diabetes.

Nebivolol is a third-generation β-blocker. Similar to carvedilol and labetalol, this β-blocker results in vasodilation. However, carvedilol and labetalol cause vasodilation because of their ability to block α_1-receptors, while nebivolol causes vasodilation through the release of nitric oxide. There are no proven long-term clinical benefits of the nitric oxide effects seen with nebivolol, but this might explain a lower risk of β-blocker–associated fatigue, erectile dysfunction, and metabolic side effects (eg, hyperglycemia) with this agent.

Alternative Agents

⑬ Alternative antihypertensive agents may be used as add-on therapy to provide additional BP lowering in patients who are already treated with combination therapy consisting of first-line antihypertensives.

α_1-Blocker

Selective α_1-receptor blockers (doxazosin, prazosin, and doxazosin) work in the peripheral vasculature and inhibit the uptake of catecholamines in smooth muscle cells resulting in vasodilation and BP lowering.

Doxazosin was one of the original treatment arms of the ALLHAT. However, it was stopped prematurely when more secondary endpoints of stroke, HF, and CV events were seen with doxazosin than chlorthalidone.[33] These data demonstrated that thiazides are superior to α_1-blockers in preventing CV events in patients with hypertension. Therefore, α_1-blockers should only be used in combination with first-line antihypertensive agents.

An α_1-blocker can provide symptomatic benefits in men with benign prostatic hypertrophy. These agents block postsynaptic α_1-adrenergic receptors located on the prostate capsule, causing relaxation and decreased resistance to urinary outflow. However, when used to lower BP, they should only be in addition to first-line antihypertensive agents.

A potentially severe side effect of an α_1-blocker is a "first-dose" phenomenon characterized by transient dizziness or faintness, palpitations, and even syncope within 1 to 3 hours of the first dose. This adverse reaction can also happen after a dose increase. These episodes are accompanied by orthostatic hypotension and can be mitigated by taking the first dose and subsequent first increased doses at bedtime. Because orthostatic hypotension and dizziness often persist with chronic administration, these agents should be used cautiously in older patients that are at an increased risk of falls. Sodium and water retention can occur with higher doses and sometimes even with chronic administration of low doses. Therefore, these agents are most effective when given in combination with a thiazide to maintain antihypertensive efficacy and minimize potential edema.

Aliskiren

Aliskiren is the only direct renin inhibitor. This drug blocks the RAAS at its point of activation, which results in reduced plasma renin activity and BP lowering.

The role of this drug class in the management of hypertension is limited. Since aliskiren is a RAAS blocker, it should not be used in combination with an ACEi or an ARB because of a higher risk of serious adverse effects without providing any additional reduction in CV events.[1]

Many of the cautions and adverse effects observed with an ACEi or ARB apply to aliskiren. Aliskiren should never be used in pregnancy due to the known teratogenic effects of using other drugs that block the RAAS system. Angioedema has also been reported in patients treated with aliskiren, as well as increases in serum creatinine and serum potassium values. The mechanisms of these adverse effects are likely similar to those with an ACEi or ARB. It is reasonable to utilize similar monitoring strategies by measuring serum creatinine and serum potassium in patients treated with aliskiren.

Central α_2-Agonist

Clonidine, guanfacine, and methyldopa lower BP primarily by stimulating α_2-adrenergic receptors in the brain. This stimulation reduces sympathetic outflow from the vasomotor center in the brain and increases vagal tone. It is also believed that peripheral stimulation of presynaptic α_2-receptors may further reduce sympathetic tone. Reduced sympathetic activity together, with enhanced parasympathetic activity, can decrease heart rate, CO, TPR, plasma renin activity, and baroreceptor reflexes. Clonidine is usually reserved for resistant hypertension, and methyldopa, when used, is primarily for pregnancy-induced hypertension.

Chronic use of centrally acting α_2-agonist results in sodium and water retention, which is most prominent with methyldopa. Low doses of clonidine and guanfacine can be used to treat hypertension without the addition of a thiazide. However, methyldopa should be given in combination with a thiazide to avoid blunting the antihypertensive effect that happens with prolonged use when treating chronic hypertension (but not in pregnancy). Sedation and dry mouth are common anticholinergic side effects that typically improve with chronic use of low doses, but they are more troublesome in older patients. As with other centrally acting antihypertensives, depression can occur, especially with high doses. The incidence of orthostatic hypotension and dizziness is higher than with other antihypertensive agents, so they should be used cautiously in the elderly. Lastly, clonidine has a relatively high incidence of anticholinergic side effects (sedation, dry mouth, constipation, urinary retention, and blurred vision). Thus, it should generally be avoided for chronic antihypertensive therapy in older patients.

Abrupt cessation of a central α_2-agonist may lead to rebound hypertension. This effect is thought to be secondary to a compensatory increase in norepinephrine release after abrupt discontinuation. In addition, other effects such as nervousness, agitation, headache, and tremor can also occur, which may be exacerbated by concomitant β-blocker use, particularly with clonidine. Thus, if clonidine is to be discontinued, it should be tapered. For patients who are receiving concomitant β-blocker therapy, the β-blocker should be gradually discontinued first several days before gradual discontinuation of clonidine. Considering the increased risk of adverse effects and the need for frequent administration with the oral dosage formulation, which increases the risk of rebound hypertension during periods of nonadherence, the transdermal form rather than tablets should be used when clonidine therapy is needed.[69]

Methyldopa can cause hepatitis or hemolytic anemia, although this is rare. Methyldopa should be quickly discontinued if persistent increases in serum hepatic transaminases or alkaline phosphatase are detected because this may indicate the onset of fulminant life-threatening hepatitis. Coombs-positive hemolytic anemia occurs in <1% of patients receiving methyldopa, although 20% exhibit a positive direct Coombs test without anemia. For these reasons, methyldopa has limited use in the routine management of hypertension, except in pregnancy.

Direct Arterial Vasodilator

Hydralazine and minoxidil directly relax arteriolar smooth muscle resulting in vasodilation and BP lowering. They exert little to no venous vasodilation. Both agents cause potent reductions in perfusion pressure that activate baroreceptor reflexes. Activation of baroreceptors results in a compensatory increase in sympathetic outflow, which leads to an increase in heart rate, CO, and renin release. Consequently, tachyphylaxis (loss of antihypertensive effect) can develop with continued use. This compensatory baroreceptor response can be counteracted by concurrent use of a β-blocker.

All patients receiving hydralazine or minoxidil for chronic therapy should first receive both a thiazide and a β-blocker. Direct arterial vasodilators can precipitate angina in patients with stable ischemic heart disease unless the baroreceptor reflex mechanism is blocked with a β-blocker (diltiazem or verapamil can be used as an alternative to β-blockers for this purpose). The side effect of sodium and water retention is significant but is minimized by using a thiazide concomitantly.

One side effect unique to hydralazine is a dose-dependent drug-induced lupus-like syndrome. Hepatic *N*-acetyltransferase eliminates hydralazine. This enzyme displays genetic polymorphism, and "slow acetylators" are especially prone to develop drug-induced lupus with hydralazine. This syndrome is more common in women and is reversible on discontinuation. Drug-induced lupus may be avoided by using less than 200 mg of hydralazine daily. Because of side effects, hydralazine has limited clinical use for chronic management of hypertension. However, it is especially useful for patients with severe CKD and kidney failure. When used in combination with isosorbide dinitrate, hydralazine has been shown to reduce the risk of CV events in Black patients with HFrEF when added to a standard regimen of a diuretic, ACEi, or ARB, and evidence-based β-blocker therapy.[44]

Minoxidil is a more potent vasodilator than hydralazine. Therefore, the compensatory increases in heart rate, CO, renin release, and sodium retention are even more dramatic. Due to significant water retention, a loop diuretic is often more effective than a thiazide in patients treated with minoxidil. A troublesome side effect of minoxidil is hypertrichosis (hirsutism), presenting as increased hair growth on the face, arms, back, and chest. Hypertrichosis usually ceases when the drug is discontinued. Other minoxidil side effects include pericardial effusion and a nonspecific T-wave change on the electrocardiogram. Minoxidil is reserved for resistant hypertension as an alternative to hydralazine.

Combination Therapy

⑬ A combination of two antihypertensive drugs is recommended for patients initially presenting with stage 2 hypertension.[1] Using a fixed-dose combination product is an option for these types of patients and has been shown to improve adherence. Initial two-drug combination therapy may also be appropriate for patients with multiple compelling indications for different antihypertensive agents. Moreover, combination therapy is often needed to control BP in patients who are already treated with drug therapy.[1]

The long-term safety and efficacy of initial two-drug therapy for hypertension were evaluated in the ACCOMPLISH trial.[83] This was a prospective, randomized, double-blind trial in 11,506 patients with hypertension and other CV risk factors. All these patients either had stage 2 hypertension or were on antihypertensive drug therapy at enrollment. Patients were randomized to receive either benazepril-with-hydrochlorothiazide or benazepril-with-amlodipine as initial drug therapy. Treatment was titrated to a goal BP of <140/90 mm Hg for most patients and <130/80 mm Hg for patients with diabetes or CKD.

The trial was terminated early after a mean of 36 months because the incidence of CV events was 20% lower in the benazepril-with-amlodipine group compared with the benazepril-with-hydrochlorothiazide group. What is most important for clinical practice is that this trial established that initial two-drug therapy for stage 2 hypertension was safe and effective. Mean BP measurements were 132/73 and 133/74 mm Hg in the benazepril-with-amlodipine and benazepril-with-hydrochlorothiazide groups.

The ACCOMPLISH trial established initial two-drug antihypertensive therapy as an evidence-based strategy to treat hypertension. Clinicians should consider this study as justification for implementing initial two-drug therapy antihypertensive regimens in appropriate patients. Moreover, the ACCOMPLISH trial demonstrated that the combination of an ACEi with a dihydropyridine CCB was more effective in reducing CV events than the combination of an ACEi with hydrochlorothiazide. However, thiazides are effective at lowering BP, particularly chlorthalidone and indapamide, especially when combined with other agents, and hydrochlorothiazide is available in many fixed-dose combination products.

Optimal Use of Combination Therapy

Clinicians should anticipate the need for combination therapy to control BP in most patients. Using low-dose combinations also provides greater BP reductions than high doses of single agents, with fewer drug-related side effects.[71] Contrary to popular myth, appropriately increasing the number of antihypertensive medications to attain goal BP values does not increase the risk of adverse effects. The American Society of Hypertension has recommended three categories of combination therapy (see Box B).[84] Preferred combinations are ideal for lowering BP, have complementary mechanisms of action, and use evidence-based first-line agents. Acceptable combinations may not provide all of the benefits that preferred combinations do and may have additive side effect profiles. Less-effective combinations are limited in their overall benefits and should only be used when necessary, except when treating compelling indications.

Box B

American Society of Hypertension Recommendations for Combination Therapy

Preferred	Acceptable	Less Effective
ACEi/CCB ARB/CCB ACEi/thiazide ARB/thiazide	β-Blocker/thiazide CCB (dihydropyridine)/β -blocker CCB/thiazide Thiazide/potassium-sparing diuretic	ACEi/β -blocker ARB/β -blocker CCB (nondihydropyridine)/β -blocker Centrally acting agent/β -blocker

Data from Reference 85.

Some combinations should be avoided when treating hypertension. As previously discussed, the ON-TARGET demonstrated that using an ACEi with an ARB in the management of hypertension resulted in no additional reduction in the incidence of CV events.[85] Moreover, this combination resulted in a higher risk of adverse events, which was also demonstrated in other trials. These same negative effects are seen when aliskiren is used in combination with an ARB.[86] These combinations (using two RAAS blockers together) should be avoided in the management of hypertension.[1] Other combinations, such as a thiazide with a potassium-sparing diuretic, both of which have overlapping mechanisms of action, should be implemented only to minimize hypokalemia; not for additional BP lowering. Combining two CCBs, a dihydropyridine with a nondihydropyridine, can provide additional BP lowering but has limited use in the routine management of most patients. Under no circumstance should two drugs from the exactly same class of medications be used to treat hypertension.

Fixed-Dose Combination Products

Many fixed-dose combination products are available, and nearly all are generic (see Table 30-9). Most combination products contain a thiazide and have multiple dose strengths. Individual dose titration is more complicated with fixed-dose combination products, but this strategy can reduce the number of daily tablets/capsules and simplify regimens to improve adherence by decreasing pill burden. This alone may increase the likelihood of achieving or maintaining goal BP values and is recommended to improve adherence.[1,87] Most generic combination products are less expensive to patients and health systems. Nonadherence rates are lower when fixed-dose combination products are used to treat hypertension compared with using free drug components (separate pills) to treat hypertension and therefore is recommended preferentially.[1]

TABLE 30-9

Fixed-Dose Combination Products

Combination	Medication (Brand Name)
ACEi with CCB	• Amlodipine/benazepril (Lotrel) • Perindopril/amlodipine (Prestalia) • Trandolapril/verapamil (Tarka)
ARB with CCB	• Amlodipine/olmesartan (Azor) • Telmisartan/amlodipine (Twynsta) • Valsartan/amlodipine (Exforge)
ACEi with a thiazide	• Benazepril/hydrochlorothiazide (Lotensin HCT) • Captopril/hydrochlorothiazide (Capozide) • Enalapril/hydrochlorothiazide (Vaseretic) • Fosinopril/hydrochlorothiazide (Monopril HCT) • Lisinopril/hydrochlorothiazide (Prinizide, Zestoretic) • Moexipril/hydrochlorothiazide (Uniretic) • Quinapril/hydrochlorothiazide (Accuretic)
ARB with a thiazide	• Azilsartan/chlorthalidone (Edarbyclor) • Candesartan/hydrochlorothiazide (Atacand HCT) • Eprosartan/hydrochlorothiazide (Teveten HCT) • Irbesartan/hydrochlorothiazide (Avalide) • Losartan/hydrochlorothiazide (Hyzaar) • Olmesartan/hydrochlorothiazide (Benicar HCT) • Telmisartan/hydrochlorothiazide (Micardis HCT) • Valsartan/hydrochlorothiazide (Diovan HCT)
β-Blocker with a thiazide	• Atenolol/chlorthalidone (Tenoretic) • Bisoprolol/hydrochlorothiazide (Ziac) • Metoprolol succinate/hydrochlorothiazide (Dutoprol) • Metoprolol tartrate/hydrochlorothiazide (Lopressor HCT) • Nadolol/Bendroflumethiazide (Corzide) • Propranolol/hydrochlorothiazide (Inderide)
Direct renin inhibitor with thiazide	Aliskiren/hydrochlorothiazide (Tekturna HCT)
Mineralocorticoid receptor antagonist with thiazide	Spironolactone/hydrochlorothiazide (Aldactazide)
ARB with CCB with a thiazide	• Amlodipine/valsartan/hydrochlorothiazide (Exforge HCT) • Olmesartan/amlodipine/hydrochlorothiazide (Tribenzor)

Chronotherapy

Chronotherapy refers to targeting medication release and its effects at specific times of the day. The rationale behind chronotherapy in hypertension is that blunting the early morning BP surge may result in more significant reductions in CV events than dosing conventional antihypertensive products in the morning.

Two nondihydropyridine CCBs, sustained-release verapamil (Verelan PM) and long-acting diltiazem (Cardizem LA), are designed to target the circadian BP rhythm. When dosed in the evening, the drug is released during the early morning hours when BP first increases. However, evidence from the Controlled Onset Verapamil Investigation of Cardiovascular End-Points (CONVINCE) trial showed that chronotherapeutic verapamil was similar to, but not better than, a thiazide–β-blocker–based regimen for CV events.[27]

The Hygia Chronotherapy Trial sought to assess whether dosing one or more antihypertensives at bedtime reduced CVD events more than upon waking.[88] The trial reported that evening dosing dramatically reduced CV events and CV death. However, results of the Hygia trial should be viewed cautiously due to several issues, including the methods (eg, open-label design, statistics used), and the magnitude of benefit on CV outcomes was inconsistent with the minimal BP difference between groups (1 mm Hg). Therefore, data are lacking based on the current evidence, demonstrating an advantage for chronotherapy in treating hypertension.

Pharmacoeconomic Considerations

The cost of effectively treating hypertension based on estimated annual healthcare expenditures is approximately $2,000 more for patients with hypertension than without hypertension.[89] The average yearly direct and indirect cost of hypertension from 2016 to 2017 was $52.4 billion.[90,91] However, costs of care are offset by savings that would be realized by reducing CV morbidity and mortality. Costs related to treating CV events (eg, MI, end-stage kidney failure) can drastically increase healthcare costs.

Antihypertensive drug costs are generally inexpensive and are not a significant portion of the total cost of hypertensive care. Nearly all antihypertensive agents, including first-line antihypertensive drug classes (ACEis, ARBs, CCBs, and thiazides), are generic. Many are available on discount formularies, including many generic fixed-dose combinations.

It is crucial to identify ways to control the cost of care without increasing the morbidity and mortality associated with uncontrolled hypertension. Using evidence-based pharmacotherapy will save costs. An ACEi, ARB, CCB, and thiazide are all first-line treatment options in most patients without compelling indications, and with few exceptions, are inexpensive. Utilizing generic agents, either as monotherapy or combined, is appropriate under nearly all circumstances in hypertension management. Use of once-daily and fixed-dose generic combination antihypertensives that are economical is preferred.[1]

Team-Based Collaborative Care

Team-based care for patients with cardiovascular disease is optimal for the comprehensive care of patients.[1] A collaborative approach to the management of hypertension is a proven strategy that improves goal BP attainment rates.[1] Ideal patient care models are interprofessional and utilize physicians, pharmacists, nurses, and other healthcare professionals.

With the advent of healthcare reform, collaborative team-based approaches to chronic diseases are viewed as high-quality and cost-effective improvement modalities. Within these models, pharmacists have been proven to be an effective component of team-based models not only in a community pharmacy or ambulatory clinic settings[92] but also in community outreach sites such as barbershops.[93] In addition to optimizing the selection and implementation of antihypertensive drug therapy and increased attainment of goal BP, clinical interventions by pharmacists have been proven to reduce the risk of adverse drug events and medication errors in ambulatory patients with CV disease.[94] Pharmacists have a substantial effect in various roles in clinical settings, through comprehensive medication management, optimization of drug use, avoidance of adverse drug events, and patient education.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring the Pharmacotherapy Plan

Routine, ongoing monitoring to assess the desired effects of antihypertensive therapy (efficacy, including BP goal attainment), undesired adverse effects (side effects and toxicity), and disease progression is needed in all patients treated with antihypertensive drug therapy.

Efficacy

The most important strategy to prevent CV morbidity and mortality from CV events in hypertension is BP control to a goal (see Box A). Treating to a goal BP of <130/80 mm Hg should be attained in older patients and those with isolated systolic hypertension. For older patients, actual BP lowering can occur at a more gradual pace to avoid orthostatic hypotension. Modifying other CV risk factors (eg, smoking, dyslipidemia, diabetes) is also essential.

Both clinic-based and self-measurement home BP monitoring are important components for monitoring and managing hypertension. Patients should be encouraged to obtain a validated home BP monitor, record the results, and send or bring them to follow-up clinic visits. BP response should be evaluated in the clinic 4 weeks after initiating or making changes in therapy and results compared to home BP readings. Once goal BP is attained, clinic BP monitoring can be done every 3 to 6 months. More frequent evaluations are required for patients with a history of poor control, nonadherence, other significant comorbidities, or symptoms of adverse drug effects.

Automated ABP monitoring can be useful clinically to establish effective 24-hour control. This type of monitoring may become the standard of care in the future because evolving data have demonstrated significant benefits of using these types of measurements to diagnose hypertension, confirm white coat or masked uncontrolled hypertension, and could be a stronger predictor of CVD.[1]

For patients self-measuring their BP at home, it is important that they measure during the early morning hours, taking at least two measurements 1 minute apart before taking antihypertensive medications, for most days and then in the evening on alternate days of the week using appropriate technique.[1] BP measurements should be recorded daily, or ideally, a monitor with a built-in memory should be used. Patients should be instructed to bring their actual measurements and/or BP monitor with built-in memory to follow-up clinic appointments, and any changes to drug therapy should be based on an average BP reading from two or more occasions.[1]

Side Effects and Toxicity

The most common side effects associated with each class of antihypertensive agents were discussed in the First-Line Antihypertensive Agents and “Alternative Agents and laboratory parameters for first-line agents are listed in Table 30-10. Laboratory monitoring should typically occur 4 weeks after starting a new agent or dose increase, and then every 6 to 12 months in stable patients. Additional disease-specific monitoring might be needed (eg, diabetes, dyslipidemia, gout) depending on which agents are used. Moreover, patients treated with a mineralocorticoid receptor antagonist (eplerenone or spironolactone) should ideally have potassium concentrations and kidney function assessed within 3 days of initiation and again at 1 week to detect potential hyperkalemia, especially for patients at high risk for hyperkalemia. The occurrence of an adverse drug event may require dosage reduction or substitution with an alternative antihypertensive agent.

TABLE 30-10

Routine Monitoring for Select Antihypertensive Agents

Class	Parameters
ACEi	BP; BUN/serum creatinine; serum potassium
ARB	BP; BUN/serum creatinine; serum potassium
β-Blocker	BP; heart rate
Calcium channel blocker	BP; heart rate
Mineralocorticoid receptor antagonist	BP; BUN/serum creatinine; serum potassium
Thiazide	BP; BUN/serum creatinine; serum electrolytes (potassium, magnesium, sodium); uric acid (for thiazides)

Disease Progression

Patients should be monitored for signs and symptoms of hypertension-associated complications. A careful history for ischemic chest pain (or pressure), palpitations, dizziness, dyspnea, orthopnea, headache, sudden change in vision, one-sided weakness, slurred speech, and loss of balance should be taken to determine the presence of CV and cerebrovascular disease. Other monitoring parameters that may be used include funduscopic changes on an eye examination, LVH on electrocardiogram, albuminuria, and changes in kidney function by calculating estimated GFR. These parameters should be monitored periodically because any sign of deterioration requires additional assessment and follow-up.

Adherence and Persistence

Poor medication use behaviors and lack of persistence with antihypertensive pharmacotherapy is a major problem and associated with significant increases in costs due to the development of complications. Since hypertension is nearly always an asymptomatic disease, poor adherence is frequent, particularly in newly treated patients. Up to 25% of patients do not fill their initial prescription for antihypertensive medication, and during the first year of treatment, an average patient possesses their BP medication only half of the time.[1] Long-term risk of CV events can be significantly reduced when patients adhere to their antihypertensive drug therapy. Therefore, it is imperative to assess patient adherence and medication-taking behavior on a regular basis.

Improving adherence to antihypertensive treatment and hypertension control requires a multifactorial approach.[1] These include interventions aimed at the patient, provider, and health-system level. Examples can include (a) focusing on clinical outcomes (eg, following national guidelines, use of once-daily antihypertensives and combination rather than free individual components, encouraging self-monitoring of BP), (b) empowering informed activated patients (eg, behavioral and motivational strategies, use of pillboxes, systems to prompt patients to refill prescriptions), (c) implementing a team approach (eg, collaborative interprofessional models of care), (d) use of telehealth strategies, and (e) advocating for health policy reform (eg, use of performance measures, reimbursement for telehealth strategies).

After identifying less than optimal adherence in a patient with hypertension, appropriate patient education, counseling, and intervention should occur. Once-daily regimens are recommended in most patients to improve adherence. Some patients may incorrectly believe that aggressive treatment may negatively impact the quality of life and thus result in nonadherence. However, several studies have found that most patients feel better once their BP is controlled, and patients should be aware of this. Patients on antihypertensive therapy should be questioned periodically about changes in their general health perception, physical functioning, and overall satisfaction with treatment. Lifestyle modifications should always be recommended to augment antihypertensive drug therapy and provide other potential health benefits. Persistence with lifestyle modifications should also be continually encouraged.

Hypertensive Urgencies and Emergencies

Both hypertensive urgencies and emergencies (aka hypertensive crisis) are characterized by elevated BP, typically >180/120 mm Hg.[1] However, the need for urgent or emergent antihypertensive therapy must be determined based on the presence of acute or immediately progressing end-organ injury, not elevated BP alone. Urgencies are not associated with acute or immediately progressing end-organ injury, while emergencies are. Examples of acute end-organ injury include encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, unstable angina, acute renal failure, and eclampsia.

Hypertensive urgencies are ideally managed by adjusting maintenance therapy, whereas hypertensive emergencies require immediate BP reduction parenteral agents to limit new or progressing end-organ damage. The Acute Hypertensive Crisis Chapter (Chapter e31) discusses the pathophysiology and pharmacotherapeutic treatment of hypertensive urgencies and emergencies.

CONCLUSIONS

Hypertension is a common medical condition in the United States with significant health consequences if not controlled. Treatment of patients with hypertension should include both lifestyle modifications and pharmacotherapy. Evidence from outcome-based clinical trials has definitively demonstrated that treating hypertension reduces the risk of CV events and subsequently reduces morbidity and mortality. Moreover, evidence evaluating individual drug classes has resulted in an evidence-based approach to selecting pharmacotherapy in an individual patient. An ACEi, ARB, CCB, and thiazide are all first-line agents. Data suggest that using a β-blocker first-line to treat patients with hypertension, without the presence of a compelling indication, is better than not treating hypertension. However, β-blocker therapy is not as beneficial in reducing the risk of CV events compared with ACEi-, ARB-, CCB-, or thiazide-based therapy and is not a first-line therapy option without an appropriate compelling indication.

Patients should be treated to a goal BP value. In addition to selecting an appropriate antihypertensive regimen, attaining a goal BP is also of paramount importance to ensure a maximum reduction in risk for CV events is provided. A BP goal of <130/80 mm Hg is recommended for most patients with hypertension. Most patients with hypertension require more than one drug to attain goal BP values; therefore, combination therapy should be anticipated.

Optimizing hypertension management can be achieved in many ways. Team-based approaches to implementing care and attaining goal BP values are preferred. Judicious use of cost-effective medications and fixed-dose combination products should always be considered to improve the sustainability of treatment. Lastly, interventions to reinforce adherence and lifestyle modifications are needed for the comprehensive management of hypertension.

SELF-ASSESSMENT QUESTIONS

Use the following scenario for the next two questions: A 78-year-old Hispanic man has a past medical history of hypertension for 10 years. His BP today is 158/82 mm Hg (156/84 mm Hg when repeated), heart rate is 70 beats/min, serum creatinine is 1.2 mg/dL (106 µmol/L) (eGFR 58 mL/min/1.73m^2), and potassium is 4.3 mEq/L (mmol/L). He is adherent with benazepril 40 mg daily and amlodipine 10 mg daily, weighs 93 kg, is 67″ (170 cm) tall (BMI 32 kg/m^2), smokes one-half pack cigarettes daily, and consumes two to three ethanol-containing drinks weekly.

1. Which of the following is the most appropriate medication to add to his antihypertensive regimen?
   - A. Verapamil
   - B. Irbesartan
   - C. Chlorthalidone
   - D. Metoprolol succinate
2. Which of the following lifestyle changes would most likely produce the greatest decrease in BP?
   - A. Weight loss of 5 kg
   - B. Smoking cessation
   - C. Decrease dietary sodium by 500 mg/day

D. Decreasing ethanol consumption by 50%

Use the following scenario for the next three questions: A 40-year-old black woman has a BP measurement of 150/110 mm Hg when she first arrives for a routine physical examination by a medical assistant. She has no previous history of hypertension. She is extensively interviewed and examined, and has no signs of acute or chronic hypertension-associated end-organ damage. Her physician measures her BP again 20 minutes later, and it is 142/98 mm Hg (140/100 mm Hg when repeated). Her most recent fasting lipid panel was also normal, and her 10-year ASCVD risk score is 1.2%. She is instructed to measure her BP at home twice each morning. After 2 weeks, her average home BP is 138/96 mm Hg.

3. Which of the following is the most accurate clinical assessment of her present situation?

   A. White coat hypertension

   B. Elevated blood pressure

   C. Stage 1 hypertension

   D. Stage 2 hypertension

4. Which of the following is the most appropriate BP goal in this patient?

   A. <120/80 mm Hg

   B. <130/80 mm Hg

   C. <140/90 mm Hg

   D. <150/90 mm Hg

5. Which of the following is the most appropriate plan for this patient now?

   A. Lifestyle modifications, continue home BP monitoring and re-evaluate in 3 months

   B. Lifestyle modifications, continue home BP monitoring, start lisinopril, and re-evaluate in 1 month

   C. Lifestyle modifications, continue home BP monitoring, start hydrochlorothiazide, and re-evaluate in 1 month

   D. Lifestyle modifications, continue home BP monitoring, start lisinopril and amlodipine, and re-evaluate in 1 month

6. A 60-year-old woman with hypertension, type 2 diabetes, and HFrEF is seen 2 months after experiencing an acute myocardial infarction. Her present BP is 110/74 mm Hg (112/76 mm Hg when repeated) and her heart rate is 60 beats/min. Her serum creatinine is 1.1 mg/dL (97 μmol/L), serum potassium is 3.5 mEq/L (mmol/L), and spot urinalysis shows 20 mg albumin/g (2.26 mg/mmol) creatinine. She currently has no peripheral or pulmonary edema. She is taking furosemide 40 mg twice daily, carvedilol 25 mg twice daily, and enalapril 20 mg twice daily. Which of the following statements is most appropriate to include when counseling this patient regarding her antihypertensive therapy?

   A. It is possible to stop enalapril because BP is at goal.

   B. Long-term benefits of carvedilol and enalapril are a reduced risk of CV events.

   C. If you experience new onset depression, you should stop taking carvedilol.

   D. If you experience dry cough, stop taking enalapril immediately because this can lead to angioedema.

7. Which of the following statements is true regarding ARBs in the treatment of hypertension?

   A. An ARB is first-line for most patients because of demonstrated BP lowering and reduced risk of CV events.

   B. The ALLHAT study showed that nonfatal MI and coronary heart disease are reduced equally with ARB therapy compared with amlodipine or chlorthalidone.

C. An ARB is preferred over an ACEi in patients with chronic kidney disease who have albuminuria.

D. An ACEi should only be added to ARB therapy in patients who are not at their BP goal value despite titrating to maximum ACEi dose.

8. Which of the following is true regarding patients with elevated BP of 120-129 mm Hg and a diastolic BP <80 mm Hg according to the 2017 ACC/AHA guideline?

A. These patients are classified as elevated BP.

B. Lifestyle modifications should be recommended with re-evaluation in 12 months.

C. Approximately 50% of these patients with elevated BP eventually develop hypertension within their lifetime.

D. These patients have equal CV risk compared to patients with normal BP values.

Use the following case for the next two questions: A 70-year-old White woman with hypertension and type 2 diabetes has been on diltiazem extended-release 360 mg daily for 6 years. She was on lisinopril several years ago, but it was stopped due to angioedema. She was first diagnosed with hypertension when her BP was 180/82 mm Hg. Today, her BP is 148/78 mm Hg (146/76 mm Hg when repeated) and her heart rate is 100 beats/min. Her urinalysis shows a spot urine albumin/creatine ratio of 100 mg/g (11.3 mg/mmol), serum creatinine is 1.6 mg/dL (141 μmol/L)(eGFR 37 mL/min/1.73m^2), potassium is 4.1 mEq/L (mmol/L), weight is 75 kg, and height is 66 inches (168 cm). These are similar to values measured 3 months ago. Her only complaint is headache.

9. Which of the following is/are routine monitoring parameters/tests that is needed because of her current antihypertensive drug therapy?

A. Heart rate

B. Serum potassium, sodium, and magnesium

C. Serum creatinine and BUN

D. Electrocardiogram

10. Olmesartan 20 mg daily is added to her regimen. Four weeks later, her BP is 136/72 and 138/74 mm Hg, serum creatinine is 1.8 mg/dL (159 μmol/L), and potassium is 4.5 mEq/L (mmol/L). Which of the following is the most appropriate option to treat this patient's hypertension?

A. Increase olmesartan to 40 mg daily.

B. Add hydrochlorothiazide 25 mg daily.

C. Add spironolactone 25 mg daily.

D. Replace olmesartan with carvedilol 12.5 mg twice daily.

11. Which of the following is true regarding the use of arterial vasodilators (hydralazine or minoxidil) in the treatment of hypertension?

A. Severe bradycardia occurs when they are used in combination with a β-blocker.

B. Both can cause severe rebound hypertension when stopped abruptly.

C. Both are poorly tolerated because of anticholinergic side effects.

D. Both should be given in combination with a diuretic and a β-blocker.

12. A 65-year-old woman with type 2 diabetes, hypertension, osteoporosis, and atrial fibrillation has a BP of 150/96 mm Hg (150/90 mm Hg when repeated), heart rate of 68 beats/min, potassium of 3.3 mEq/L (mmol/L), and a serum creatinine of 2.3 mg/dL (203 μmol/L). She reports an "allergy"

to hydrochlorothiazide (severe gout). Presently, she is on verapamil CD 480 mg daily. Which of the following drug regimens would be the most appropriate to add to her regimen?

A. Chlorthalidone 12.5 mg daily

B. Amlodipine 5 mg daily

C. Atenolol 25 mg daily

D. Valsartan 160 mg daily

13. Which of the following is preferred as add-on therapy for a patient who is post-MI (3 months ago) with a BP of 136/88 mm Hg (134/86 mm Hg when repeated) while treated with metoprolol succinate 200 mg daily?

A. Chlorthalidone

B. Verapamil

C. Amlodipine

D. Lisinopril

14. Which of the following is preferred as initial antihypertensive therapy for a 63-year-old woman who is diagnosed with hypertension and has a history of ischemic stroke (6 months ago), with a BP of 186/108 mm Hg (184/106 mm Hg when repeated)?

A. A thiazide with an ACEi

B. A thiazide with a nonselective β-blocker

C. A thiazide alone

D. An ACEi with an ARB

15. A 52-year-old man has a history of asthma, chronic stable angina, and hypertension. He is experiencing ischemic chest pain twice weekly while being treated with bisoprolol 10 mg daily. His BP is 146/90 mm Hg (144/92 mm Hg when repeated), and heart rate is 58 beats/min. Which of the following would be most appropriate to add to this patient's regimen?

A. Lisinopril 20 mg daily

B. Diltiazem SR 180 mg daily

C. Amlodipine 5 mg daily

D. Irbesartan 150 mg daily and hydrochlorothiazide 25 mg daily

Use the following case for the next three questions: A 69-year-old Black woman with a history of angioedema (from lisinopril), hypertension, and type 2 diabetes is currently receiving hydrochlorothiazide 25 mg daily and carvedilol 25 mg twice daily. Today her BP is 138/82 mm Hg (138/84 mm Hg when repeated) and heart rate is 50 beats/min. Urinalysis shows a spot urine/creatine ratio 400 mg/g (45.2 mg/mmol), serum creatinine is 1.2 mg/dL (106 μmol/L) (eGFR 57 mL/min/1.73m^2), potassium is 3.8 mEq/L (mmol/L), weight is 90 kg, and height is 65 inches (165 cm). She complains of heartburn, a dry cough, constipation, and severe fatigue especially when she tries to exercise. She normally exercises three times per week, but has not been able to since her last medical visit, and follows a DASH eating plan.

16. Which of her complaints is most likely from one of her antihypertensive medications?

A. Heartburn

B. Dry cough

C. Constipation

D. Fatigue

17. Which of the following is the most appropriate modification to her regimen?

    A. Decrease carvedilol to 12.5 mg twice daily and add lisinopril.

    B. Decrease carvedilol to 12.5 mg twice daily and add irbesartan.

    C. Stop hydrochlorothiazide and start spironolactone and felodipine.

    D. Stop carvedilol and start valsartan.

18. The patient reports taking several nonprescription medications including aspirin 81 mg daily, a multivitamin daily, acetaminophen, and loratadine. She asks you if these are safe to take because of her hypertension. Which of the following is the most appropriate response?

    A. You should stop taking these until you have discussed this with your primary care physician.

    B. Acetaminophen can increase your blood pressure; you should use naproxen instead.

    C. Loratadine can increase your blood pressure; you should use pseudoephedrine if needed.

    D. These medications are generally safe to use in patients with hypertension, even if not controlled.

19. A 55-year-old man with hypertension and no other chronic medical problems is currently treated with hydrochlorothiazide 50 mg daily, irbesartan 300 mg daily, carvedilol 25 mg twice daily, and amlodipine 10 mg daily. His BP is 144/96 mm Hg (146/94 mm Hg when repeated). He is adherent with all of these medications and with lifestyle modifications. Serum creatinine is 1.2 mg/dL (106 μmol/L), potassium is 3.7 mEq/L (mmol/L), and all other laboratory values are normal. Which of the following is the most appropriate to add to his regimen?

    A. Terazosin 2 mg daily

    B. Spironolactone 25 mg daily

    C. Clonidine 0.1 mg twice daily

    D. Chlorthalidone 25 mg daily

20. A 40-year-old man with newly diagnosed hypertension asks you for advice regarding lifestyle modifications to lower BP. He has no other past medical history, is 72 inches (183 cm) tall, weighs 120 kg, and does not follow any particular diet. He eats red meat most days of the week, eats lunch out at work Monday through Friday, eats breakfast and dinner at home most days, and drinks 1 beer/week. He does not exercise. Which of the following is an appropriate recommendation?

    A. Lose weight

    B. Increase your daily ingestion of potassium and sodium

    C. Start 60 minutes of vigorous exercise most days of the week

    D. Decrease your daily fiber intake

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The patient has uncontrolled hypertension. Although he is older, he does not have a limited life expectancy, is not living in a nursing home, a goal of <130/80 mm Hg is appropriate. He is already on two first-line agents with an ACEi and a dihydropyridine CCB. The most appropriate addition

to his current therapy would be a thiazide diuretic (see Fig. 30-2). A thiazide-type diuretic is a first-line agent for this patient who has no other compelling indications for specific antihypertensive drug therapy, and should be effective in lowering BP as an addition to his current regimen. Although verapamil is a non-dihydropyridine CCB adding it to amlodipine, which is a non-dihydropyridine CCB, not be a complimentary combination regimen. Adding irbesartan would be harmful because it is an ARB and she is already on an ACEi (benazepril) and this type of combination can increase risk of adverse effects and should be avoided.

2. **A.** Weight loss is the most likely to result in the greatest BP lowering, particularly considering the patient is obese (his BMI is ≥ 30 kg/m^2). The extent that BP is lowered with weight loss is directly associated to the amount of weight loss achieved. Smoking increases the risk of ASCVD, and smoking cessation should be recommended to reduce overall risk of ASCVD. Smoking does not increase BP chronically and it is not a secondary cause of hypertension, so smoking cessation is not a modality to lower BP. Likewise, the magnitude of sodium reduction listed (only 500 mg/day) is fairly low and is not expected to significantly lower BP. The patient's current alcohol consumption is under the current recommended maximum intake, so further restriction is not necessary. See Table 30-4.

3. **D.** This patient has several BP measurements from multiple clinical visits that are ≥130/80 mm Hg, so she meet the criteria for the diagnosis of hypertension. Because the patient's SBP is ≥140 mm Hg and diastolic is ≥90 mm Hg, she is categorized as stage 2 hypertension. She does not have white coat hypertension because her average out-of-office (home) BP measurement (138/96 mm Hg) is similar to the last BP measurements of 142/98 and 140/100 mm Hg. If her average home BP value was 130-139/80-89 mm Hg, she would be considered to have stage 1 hypertension, and if 120-129/<80 mm Hg, it would be categorized as elevated. See Table 30-3.

4. **B.** The goal BP per the 2017 ACC/AHA High Blood Pressure Guideline is <130/80 mm Hg. The option of <120/80 mm Hg is considered a normal BP, but is never a goal of therapy. The options of <140/90 or <150/90 mm Hg are no longer recommended by the 2017 ACC/AHA High Blood Pressure Guideline.

5. **D.** Lifestyle modification is always recommended for any patient, especially when BP is ≥120/80 mm Hg. Continuing home BP monitoring is reasonable because she is already doing it and home BP monitoring is a modality to engage patients with their disease and it's use is associated with a higher rate of achieving goal BP. This patient has stage 2 hypertension with diastolic BP >10 mm Hg from goal. Therefore, combination therapy with two first-line antihypertensives, in addition to lifestyle modifications, is recommended, with re-evaluation in 1 month. This would also be recommended if her systolic BP was >20 mm Hg from goal. Lifestyle modifications alone with re-evaluation in 3 months would be appropriate if she were in stage 1 hypertension because her 10-year ASCVD risk is <10%, and if continually in stage 1 after 3 to 6 months monotherapy with hydrochlorothiazide (preferred because she is a Black woman) would be reasonable. Under that circumstance, monotherapy with lisinopril (an ACEi) would be less desirable because she is African American and at age 40 may be of childbearing potential and would need to be on a reliable form of contraception if sexually active due to the potential harm of using an ACEi if she were to become pregnant. See Fig. 30-2 and Box B.

6. **B.** With a history of an acute MI as well as HFrEF, the patient has compelling indications for both an ACEi and β-blocker. These medications reduce the risk of CV events in HFrEF and in patients with stable ischemic heart disease (history of myocardial infarction). Specifically, in HFrEF carvedilol, metoprolol succinate or bisoprolol are considered proven β-blocker in HFrEF, and use of most β-blockers post-myocardial infarction is proven to reduce mortality and risk of recurrent myocardial infarction. Stopping enalapril is not reasonable considering her high ASCVD risk, even if at BP goal. Counseling patients to stop a β-blocker if they experience depression would be harmful and would induce rebound hypertension if not slowly tapered. Although cough is a risk of ACEi therapy, which is annoying, it does not lead to angioedema. See section Key Concept 10. Patients with Compelling Indications.

7. **A.** An ARB is considered a first-line agent for the treatment of hypertension. ARBs were not studied in ALLHAT, are not preferred over an ACEi in patients with CKD who have albuminuria, and should not be used in combination with an ACEi. See the "First-Line Antihypertensive Agents" section.

8. **A.** A patient with a BP of 120-129/<80 mm Hg would be considered to have elevated BP. While lifestyle recommendation is recommended for all patients with elevated BP, the re-evaluation time should be 3 to 6 months, not 12 months (Fig. 30-2). The lifetime risk of developing hypertension is higher than 90% (not 50%), and patients with elevated BP have a higher CV risk than those with normal BP values (<120/<80 mm Hg).

9. **A.** Heart rate should be routinely monitored in patients treated with a non-dihydropyridine CCBs because these types of drugs can cause bradycardia due to their ability to block AV node conduction. Serum potassium, sodium, and magnesium do not need to be monitored with CCBs as they do with other medications (eg, thiazide diuretics) because they do not change any electrolytes, including serum calcium. Serum creatinine and

BUN should not be altered with CCB therapy as they potentially are with other agents (eg, ACEi, ARB, diuretics), and an electrocardiogram is not necessary as routine monitoring for patients treated with CCBs. See Table 30-10.

10. **A.** Since the patient's BP is not at her goal of <130/80 mm Hg, and because she has a compelling indication of CKD with albuminuria, the dose of the ARB should be optimized to achieve her goal BP and to slow the progression of CKD. Adding a second agent, whether it is hydrochlorothiazide or spironolactone is not necessary at this point, because using the maximum tolerated dose of an ARB (or ACEi as an alternative) is needed because she has albuminuria. The small increase in serum creatinine is less than 30% from the baseline so there is no need to replace olmesartan with carvedilol. See the "Chronic Kidney Disease" section.

11. **D.** Both hydralazine and minoxidil cause direct arteriolar smooth muscle vasodilation, which is their primary mechanism of action that results in BP lowering. This causes a compensatory increase in sympathetic outflow, resulting in an increase in heart rate and sodium and water retention. Using a β-blocker with a diuretic is recommended to block these compensatory actions to mitigate adverse effects. Tachycardia, not bradycardia, is an adverse effect of these agents. Rebound hypertension is not associated with the abrupt cessation of therapy with hydralazine or minoxidil as it is with β-blocker or centrally acting α-agonists. In contrast to centrally acting α-agonists (especially clonidine), anticholinergic side effects are not attributed to hydralazine or minoxidil use. See the "Direct Arterial Vasodilator" section.

12. **D.** Valsartan, an ARB, is the most appropriate to add to the patient's current regimen of verapamil (a non-dihydropyridine CCB). The use of an ARB (or ACEi) with a CCB is a recommended and efficacious antihypertensive combination. Chlorthalidone would not be appropriate due to current hypokalemia, significant kidney dysfunction, and a history of severe gout with hydrochlorothiazide. The patient is already on a non-dihydropyridine CCB and a dihydropyridine CCB (amlodipine) should not be added now. A β-blocker, particularly a non-recommended one such as atenolol, would not be safe in combination with verapamil because it will increase the risk of bradycardia, especially because her current heart rate is 68 beats/min. See Table 30-5 and Box B.

13. **D.** This patient is already on appropriate first-line therapy, a β-blocker, which is proven to reduce both risk of death and recurrent MI in this type of patient with stable ischemic heart disease (his MI was 3 months ago). The preferred add-on agent for this post-MI patient that is already on a β-blocker would be an ACEi or ARB, so adding lisinopril is correct. All of the other options may be helpful in reducing BP to goal, but are not compelling indicated in a patient with stable ischemic heart disease, where β-blocker therapy is the first line, followed by the addition of an ACEi or ARB. See Fig. 30-3.

14. **A.** A history of ischemic stroke (or a transient ischemic attack) is a compelling indication for either a thiazide diuretic as monotherapy or a thiazide with an ACEi when combination therapy is needed. This patient is far from their goal of <130/80 mm Hg, thus requiring >20/10 mm Hg reduction in BP. The preferred therapy, which is compellingly indicated for this patient because of a history of ischemic stroke, is a thiazide with an ACEi. See Fig. 30-3.

15. **C.** Considering the patient has a compelling indication of stable ischemic heart disease (chronic stable angina) and is already on a β-blocker, the next most appropriate therapy to treat both his BP and ischemic chest pain is a non-dihydropyridine CCB. Therefore, adding amlodipine is correct. Adding lisinopril, or irbesartan with hydrochlorothiazide would help lower BP to goal, but will not provide relief of ischemic chest pain. This patient needs this based on their clinical presentation. Adding diltiazem would be harmful because it would cause significant bradycardia because this patient has a heart rate of 58 beats/min and is already on a β-blocker. See Calcium Channel Blocker (CCB)section.

16. **D.** The side effect of fatigue, particularly as the patient normally exercises 3 times/week, is most likely due to the use of a β-blocker (carvedilol). See β-Blockers section. Heartburn, dry cough, and constipation are common side effects of other types of antihypertensive medications (CCB and ACEi), but not hydrochlorothiazide or carvedilol.

17. **B.** Since the patient is complaining of severe fatigue which is most likely due to the β-blocker, and the fact that her heart rate is 50 beats/min (too low because it is <55), the carvedilol dose should be decreased and another agent added to improve BP control. An ACEi (lisinopril) would be inappropriate and harmful due to a history of ACEi-induced angioedema, so it is contraindicated. Since she also has type 2 diabetes with albuminuria, adding an ARB (irbesartan) is the most appropriate addition. Replacing hydrochlorothiazide with spironolactone and felodipine is not appropriate now because she has compelling indications (diabetes and CKD) that should be treated with an ACEi or ARB. Replacing carvedilol with valsartan would be appropriate for her compelling indication, but would not likely result in her achieving her BP goal of <130/80 mm Hg, and abruptly stopping carvedilol by replacing it with another agent would result in rebound hypertension. See Table 30-5.

18. **D.** None of her current OTC medications are associated with significant increases in BP, so it is safe and appropriate to inform her of this. There is no need to stop these agents, acetaminophen does not increase BP, and though loratadine does not increase BP pseudoephedrine can and should be avoided when possible in patients with uncontrolled hypertension. See Table 30-1.

19. **B.** This patient meets the criteria for resistant hypertension because he is adherent to a drug regimen that includes at least three antihypertensive medications, including a diuretic, long-acting CCB, and ACEi or ARB, all at full doses. Of note, he is also on a fourth agent (a β-blocker). Spironolactone (a mineralocorticoid receptor antagonist) is the most appropriate option for this patient with resistant hypertension and is safe based on his low-normal serum potassium. Adding terazosin, which is an α-blocker, is not reasonable because carvedilol is both an α- and β-blocker. Clonidine is appropriate ahead of a mineralocorticoid receptor antagonist in resistant hypertension and adding chlorthalidone to hydrochlorothiazide is not recommended because they are both similar diuretics. See the "Resistant Hypertension" section.

20. **A.** Because the patient has stage 2 obesity with a calculated BMI of 35.8 kg/m^2, weight loss is appropriate. While increasing potassium dietary intake is advisable, increasing sodium is not; reducing dietary sodium is a recommended and proven lifestyle modification that lowers BP. The patient should start exercising, but should not be advised to go from no exercise to 60 minutes of vigorous exercise most days of the week. This is too rapid of an introduction of exercise and is not likely to be successful. He should also increase, not decrease, his dietary fiber intake as a recommended component of a heart-healthy diet. See Table 30-4 and the "Nonpharmacologic Therapy" section.

Chapter 32: Dyslipidemia

Dave L. Dixon; Daniel M. Riche; Michael S. Kelly

KEY CONCEPTS

KEY CONCEPTS

① Lipid abnormalities increase the risk of atherosclerotic cardiovascular disease (ASCVD) which includes ischemic coronary heart disease, ischemic stroke, and peripheral arterial disease.

② Low-density-lipoprotein cholesterol (LDL-C) is the primary target to reduce the risk of ASCVD events.

③ Genetic abnormalities and environmental factors are involved in the development of dyslipidemia.

④ Therapeutic lifestyle change is the first-line therapy for any lipoprotein disorder.

⑤ If therapeutic lifestyle changes are insufficient, lipid-lowering agents should be chosen based on which lipid is at an undesirable level and the degree to which it is expected to increase the risk of ASCVD.

⑥ Statins are the drug of choice for dyslipidemia because they significantly lower LDL-C and the risk of ASCVD events, and are generally well tolerated.

⑦ If statin monotherapy is insufficient, patients may be treated with evidence-based combination therapy but should be monitored closely for drug-drug interactions.

⑧ Reducing total cholesterol and LDL-C reduces CHD and total mortality.

⑨ Lipid-lowering therapies that reduce ASCVD event rates are cost-effective.

⑩ Several novel medications including antisense oligonucleotide inhibitors of apoB, microsomal triglyceride transport protein inhibitors, adenosine triphosphate-citrate lyase (ACL) inhibitors, and proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors can be used as add-on therapy or in lieu of statin therapy in select high-risk populations.

INTRODUCTION

Cholesterol, triglycerides, and phospholipids are the major lipids that combine with proteins to be transported as complexes of lipid and proteins known as lipoproteins. Lipids, such as cholesterol and triglycerides, are insoluble in plasma, which is why the lipoproteins are required for transportation (Fig. 32-1).[1,2]

FIGURE 32-1

Intestinal cholesterol absorption and transportation. Cholesterol from food and bile enters the gut lumen and is emulsified by bile acids into micelles. Micelles bind to intestinal enterocytes and cholesterol, and other sterols are transported from the micelles to the enterocytes by sterol transporters. Triglycerides (TG) synthesized by absorbed fatty acids (FA) are incorporated into chylomicrons. Chylomicrons are released into lymphatic circulation and converted to chylomicron remnants (by losing triglyceride), and are then taken up by hepatic LDL-receptor–related protein. There are three major classes of lipoproteins in the serum. These include low-density lipoproteins (LDL), high-density lipoproteins (HDL), and very-low-density lipoproteins (VLDL). VLDL is the primary carrier of triglycerides (TG) in the circulation. Intermediate-density lipoprotein (IDL) is between VLDL and LDL and is included in LDL-C measurement (Fig. 32-2).[3]

①② Lipid abnormalities increase the risk of coronary, cerebrovascular, and peripheral vascular arterial disease collectively known as atherosclerotic cardiovascular disease (ASCVD). The ASCVD-risk assessment evaluates a 10-year ASCVD incident. Developing a first ASCVD event is defined as nonfatal myocardial infarction or coronary heart disease (CHD) death, or fatal or nonfatal stroke, over a 10-year period. Premature coronary atherosclerosis is the most common and significant consequence of dyslipidemia. The 2013 guidelines from the American Heart Association (AHA) and American College of Cardiology (ACC) state that there is no sufficient evidence to recommend treating to specific lipid targets but suggests four statin benefit patient populations.[5] Low-density lipoprotein cholesterol (LDL-C) is the primary target of lipid-lowering therapy. Methods for risk assessment were also updated, which increases the number of patients who would qualify for therapy. Primary and secondary CHD prevention measures are provided as well.[4–7]

There are several subtypes of dyslipidemias, including hypertriglyceridemia, low HDL cholesterol (HDL-C), and diabetic dyslipidemia. Hypertriglyceridemia can lead to pancreatitis when very high TG levels (>500 mg/dL [5.65 mmol/L]) are seen. High serum triglycerides should primarily be treated by achieving desirable body weight, consumption of low saturated fat and cholesterol diet, regular exercise, smoking cessation, and restriction of alcohol.[3,4] In patients with borderline-high TG but with accompanying risk factors of established congenital heart disease, family history of premature CHD, concomitant LDL-C elevation or low HDL-C, and genetic forms of hypertriglyceridemia associated with CHD, lipid-lowering therapy should be considered.[8–10]

Low HDL-C is another dyslipidemia subtype that can occur due to insulin resistance, physical inactivity, diabetes, cigarette smoking, high carbohydrate intake, and some medications. In patients with low HDL-C, the primary target remains LDL-C, but an emphasis on weight loss, increased physical activity, and smoking cessation are recommended. No randomized controlled trials (RCT) have shown a reduction in ASCVD risk by raising HDL-C levels.[3,11] Hypertriglyceridemia, low HDL-C, and minimally elevated LDL-C characterize diabetic dyslipidemia. Because the primary target is LDL-C in diabetic dyslipidemia, statins are considered the drugs of choice.[3,4,12,12,13]

EPIDEMIOLOGY

Total cholesterol and LDL-C increase throughout life in both men and women. According to AHA estimates, approximately 49% of American adults aged 20 years or older have total cholesterol levels exceeding 200 mg/dL (5.17 mmol/L).[14] The prevalence of elevated LDL cholesterol as a risk factor for death in adults has increased from 15th in 1990 to 8th in 2019.[15] Westernized societal diets high in cholesterol are a strong contributor to the increase in total and LDL-C cholesterol. In 2011, CHD caused one in every seven deaths in the United States. About one-third of treated patients are achieving their LDL-C goal; fewer than 20% of CHD patients are at their LDL-C goal. Estimates from the National Cholesterol Education Program (NCEP) state that only 26% of patients have an optimal LDL-C (<100 mg/dL [2.59 mmol/L]), and that large numbers of patients are either untreated or undertreated. Patients at the highest risk are less likely to be treated to desirable LDL-C values.[15–17] When patients who are at risk but who have not yet experienced initial cardiovascular (eg, myocardial infarction [MI]) or cerebrovascular (eg, ischemic stroke) events are treated, it is termed primary prevention. Treatment for those with manifest ASCVD is termed secondary prevention.[17] Studies, such as the Framingham Heart Study, show that risk for developing cardiovascular disease is related to the degree of LDL-C elevation in a continuous fashion.[3] Hypercholesterolemia, cigarette smoking, hypertension, diabetes, and low HDL-C levels are all additive risk factors for CHD. The risk of MI increases five to seven times with any preexisting CHD or previous MI compared to patients with no history of these. Patients with a history of CHD or MI should be screened, identified, and treated for dyslipidemias. Fifty percent of all MIs and 70% of all deaths due to CHD occur in patients with known CHD.

ETIOLOGY

③ Genetic abnormalities and environmental factors are involved in the development of dyslipidemia. The underlying causes of dyslipidemias can be categorized into two types: primary or secondary. Genetic factors that increase lipid levels can be inherited and cause primary or familial dyslipidemia. By contrast, lifestyles, diseases, medications, and diet can all lead to abnormal lipid levels and cause secondary or "acquired" dyslipidemia.

Primary or Familial Dyslipidemias

Primary or familial dyslipidemias account for a large number of cases of increased total cholesterol, LDL-C, TGs, or decreased HDL-C. There are certain familial or genetic defects that can contribute. Genetic disorders can cause an increase or decrease in different lipoproteins. Primary dyslipidemias result in an increased risk of premature ASCVD due to significant elevations in cholesterol levels. There are different types of familial dyslipidemias, including hypercholesterolemia, hypertriglyceridemia, combined hyperlipidemia, and disorders of HDL-C metabolism, and an excess of lipoproteins. Two other primary disorders include homozygous familial hypercholesterolemia (HoFH) and heterozygous familial hypercholesterolemia (HeFH). HeFH is more common with one case per 250 people versus HoFH with one case per one million people. In familial hypertriglyceridemia, TGs are elevated in the range of 200 to 500 mg/dL (2.26-5.65 mmol/L), but at times can be greater than 1,000 mg/dL (11.3 mmol/L). Patients presenting with TG concentrations greater than or equal to 500 mg/dL (5.65 mmol/L) can have eruptive xanthomas and/or acute pancreatitis. Heterozygous gene dysfunction usually causes elevations in LDL-C between 250 and 450 mg/dL (6.47-11.64 mmol/L), and homozygous patients may present with LDL-C concentrations above 500 mg/dL (12.93 mmol/L). Tendon xanthomas are thick cholesterol deposits. Xanthelasmas and arcus cornea can also occur, and these are cholesterol deposits in the eyelids and around the corneal rim.[18–20]

Secondary or Acquired Dyslipidemias

Secondary or acquired dyslipidemias can accompany genetic disorders or cause lipid imbalances. "The 4D classification" of secondary causes of dyslipidemia include diet, drugs, disorder, and diseases.[19] Regarding diet, an increase in cholesterol can be caused by excessive alcohol use, anorexia, weight gain, excessive carbohydrate intake, and high saturated fat intake. Certain medications can also contribute. For example, some medications that can increase both LDL-C and TGs include atypical antipsychotics, diuretics, beta-blockers, glucocorticoids, oral estrogen and progestin, tacrolimus, and cyclosporine.

Certain metabolism disorders can contribute to cholesterol imbalances. Nephrotic syndrome, renal failure, biliary obstruction, hypothyroidism, and pregnancy can all potentially contribute. Comorbid conditions or diseases such as hypothyroidism, pregnancy, obesity, polycystic ovarian syndrome (PCOS), uncontrolled diabetes, liver disease, chronic kidney disease can also play a role.

Although we classify the lipid disorders into primary and secondary dyslipidemias based on etiologies, most dyslipidemias are a result of a combination of both.[4,19]

PATHOPHYSIOLOGY

Lipoproteins and Cholesterol Synthesis

There are four types of lipoproteins: chylomicrons, VLDL, LDL, and HDL. These lipoproteins vary in the content of lipid and protein. The ratio of protein and lipid in these lipoproteins contributes to the function of each. Chylomicrons contain the most lipid and little protein. HDL contains the most protein and a small amount of lipids. The small amount of lipid, and in turn cholesterol, in HDL lipoproteins gives HDL the role of picking up extra cholesterol from the tissue. LDL is not necessarily "bad" cholesterol, but in excess, this generates the problem. We need cholesterol for the transportation of fats that are absorbed in our diet and delivered to our tissues. Chylomicrons are not normally in plasma during periods of fasting. In the small intestine, fats are digested and emulsified into micelles. Cholesterol is also absorbed. Fatty acids, cholesterol, and proteins or apoproteins are packaged and form chylomicrons. The chylomicrons circulate around the body and deliver lipids and TGs to tissues in need. The remaining chylomicrons are transported to the liver and bind to LDL receptors. Glucose that has also been absorbed from our diet is delivered to the liver. In the liver, glucose is converted to pyruvate and then to acetyl-CoA. Acetyl-CoA is eventually converted to cholesterol through 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase. HMG-CoA reductase is a target for statins, thus stopping cholesterol synthesis. Glycolysis also synthesizes glycerol. Combining glycerol and one fatty acid forms monoacylglycerol, and two more fatty acids form triglycerides. Triglycerides and apoproteins are packed through the Golgi apparatus and form lipoproteins. Lipoproteins contain proteins, apoproteins, TGs, phospholipids, and cholesterol. The liver does not make all lipoproteins. In fact, only empty HDL and VLDL are made in the liver. VLDL has more TGs and lipids than HDL. VLDL transports these lipids and TGs to tissues in need of energy or storage. Adipose tissue stores fat, and many tissues use fatty acids for energy. VLDL is transported across lipase, which changes the VLDL to IDL or intermediate-density lipoproteins. IDL can then be converted to LDL. LDL mainly transports cholesterol to body tissues, which is why LDL contains the most cholesterol. Tissues need cholesterol to make hormones and maintain cell membrane integrity. Once LDL gives these tissues cholesterol, it returns to the liver. LDL binds to LDL receptors and is then either recycled to make more lipoproteins or excreted into the bile. Any excess cholesterol is excreted into the bile, so the body maintains cholesterol balance. HDL or empty HDL plays a role in picking up any or excess cholesterol and returning it to the liver. The full HDL containing the picked up cholesterol binds to scavenger receptors. They are then either recycled or excreted depending on how much cholesterol is needed.[1]

Lipid Metabolism and Transport

Cholesterol is water-insoluble so it cannot circulate through blood without help. Lipoproteins are large carrier proteins to help with transport because they are water-soluble. This allows major lipids to be circulated through the blood. Lipoproteins vary in characteristics depending on the amount of cholesterol, TG, and apolipoproteins. All lipoproteins also have something called apolipoproteins on its surface. Apolipoproteins are necessary for the assembly and secretion of lipoproteins. They are also major structural components of lipoproteins that have ligands for binding to receptors or cell surfaces. These are the cofactors for the activation of enzymes. Apolipoproteins have various functions that transport lipids from sites of absorption to sites where they are used. Apolipoprotein B containing lipoproteins, known as non- HDL, make up the lipid-delivery pathway. Apolipoprotein A-1 or HDL participates in reverse cholesterol transport. ApoB containing lipoproteins arise from two sources, one being intestinal ApoB-48 and the other hepatic ApoB-100 lineage. ApoB containing lipoproteins are secreted from the intestine or liver into the plasma. Apolipoproteins E, C-II, and C-III are secreted with them. These may also be acquired from HDL. Apolipoprotein remodeling begins, and ApoC-II activates lipoprotein lipase (LPL), which hydrolyzes the lipoprotein core TGs into free fatty acids. The fatty acids exit and the lipoproteins become smaller and smaller. Remodeling of the ApoB-100 hepatic lipoprotein, another step by hepatic lipase (HL) is needed to convert IDL to LDL. Most ApoB remnants are recycled to the liver by the LDL-receptor–related protein (LRP). They can have other metabolic requirements, too. Excess ApoB particles can invade arterial walls and become oxidized. Once oxidized, they are taken up by macrophage scavenger receptors creating foam cells that lead to atheroma.

ApoA-1 or HDL pathways are believed to protect our bodies from atherogenesis. HDL has two major protective roles in preventing atherogenesis. Reverse cholesterol transport is the transfer of excess cholesterol from peripheral tissues by HDL. ApoA-1 is secreted from the liver or intestine and is transported to the cells to remove excess cholesterol. HDL has several cholesterol removing mechanisms. Upregulation of the ATP-binding cassette transporter or ABCA-1 transporter is triggered by excess cholesterol in the macrophages. ABCA-1 harvests free cholesterol and delivers it to the cell membrane. The free cholesterol is esterified by lecithin-cholesterol acyltransferase (LCAT). The cholesterol ester moves to the core of the lipoprotein forming the mature HDL3. Further removal of cholesterol by HDL3 occurs through scavenger receptor class B type 1, or SR-B1 receptors and is acted on by LCAT, which expands to HDL2. ABCA-1 and SR- B1 are key for cholesterol efflux. HDL2 cholesterol is transferred to ApoB containing lipoproteins. HDL now has one of three options: HDL triglycerides may be hydrolyzed by HL back into HDL3; HDL2 can return to the liver and through SR-B1 converted back to HDL3; or HDL2 may be catabolized by the liver. All of these systems work together to maintain cholesterol homeostasis (Figs. 32-3 and 32-4).[1]

Familial Hypercholesterolemia

Familial hypercholesterolemia is characterized by (a) a selective elevation in the plasma level of LDL; (b) deposition of LDL-derived cholesterol in tendons (xanthomas) and arteries (atheromas); and (c) inheritance as an autosomal dominant trait with homozygotes more severely affected than heterozygotes. The primary defect in familial hypercholesterolemia is the inability to bind LDL to the LDL receptor (LDL-R) or, rarely, a defect of internalizing the LDL-R complex into the cell after normal binding. This leads to a lack of LDL degradation by cells and unregulated biosynthesis of cholesterol, with total cholesterol and LDL-C being inversely proportional to the deficit in LDL receptors. Homozygotes (prevalence 1 in 1,000,000) have severe hypercholesterolemia (650-1,000 mg/dL [16.8-25.9 mmol/L]), with the early appearance of cutaneous xanthomas and fatal CHD generally before the age of 20 and have essentially no functional LDL receptors. Heterozygotes have only about one-half of the normal number of LDL receptors, total cholesterol levels in the range of 300 to 600 mg/dL (7.76-15.52 mmol/L), and cardiovascular events beginning in the third and fourth decades of life.

Secondary causes of dyslipidemia exist and that several drugs and conditions may contribute to abnormal lipid levels (Table 32-1). These secondary forms of dyslipidemia should be managed by addressing the underlying abnormality, including the modification of drug therapy when appropriate.

TABLE 32-1

Secondary Causes of Lipoprotein Abnormalities

Hypercholesterolemia	Hypothyroidism Obstructive liver disease Nephrotic syndrome Anorexia nervosa Acute intermittent porphyria Drugs: progestins, thiazide diuretics, glucocorticoids, beta-blockers, isotretinoin, protease inhibitors, cyclosporine, mirtazapine, sirolimus
Hypertriglyceridemia	Obesity Diabetes mellitus Lipodystrophy Glycogen storage disease Ileal bypass surgery Sepsis Pregnancy Acute hepatitis Systemic lupus erythematosus Monoclonal gammopathy: multiple myeloma, lymphoma Drugs: alcohol, estrogens, isotretinoin, beta-blockers, glucocorticoids, bile-acid resins, thiazides, asparaginase, interferons, azole antifungals, mirtazapine, anabolic steroids, sirolimus, bexarotene
Hypocholesterolemia	Malnutrition Malabsorption Myeloproliferative diseases Chronic infectious diseases: tuberculosis Monoclonal gammopathy
Low HDL	Malnutrition Obesity Drugs: non-ISA beta-blockers, anabolic steroids, probucol, isotretinoin, progestins

Pathogenesis of Atherosclerotic Cardiovascular Disease

The “response-to-injury” hypothesis states that risk factors such as oxidized LDL, mechanical injury to the endothelium, excessive homocysteine, immunologic attacks, or infection-induced changes in endothelial and intimal function lead to endothelial dysfunction and a series of cellular interactions that culminate in atherosclerosis. C-reactive protein (CRP) is an acute-phase reactant and a marker for inflammation. Measuring one’s CRP levels by means of a high-sensitivity CRP may be useful in identifying patients at risk for developing CAD. Lipid abnormalities increase the risk for CHD and cerebrovascular morbidity and mortality. The eventual outcomes of this atherogenic cascade are clinical events such as angina, MI, arrhythmias, stroke, peripheral arterial disease, abdominal aortic aneurysm, and sudden death. Atherosclerotic lesions are thought to arise from transport and retention of plasma LDL-C through the endothelial cell layer into the extracellular matrix of the subendothelial space. Once in the artery wall, LDL-C is chemically modified through oxidation and nonenzymatic glycation. Mildly oxidized LDL-C then recruits monocytes which transforms into macrophages in the artery wall. Macrophages accelerate LDL-C oxidation and apolipoprotein B accumulation and alter the receptor-mediated uptake of LDL-C into the artery wall from the usual LDL-R to a "scavenger receptor" not regulated by the cell content of cholesterol. Oxidized LDL-C increases plasminogen inhibitor levels (promotion of coagulation), induces the expression of endothelin (vasoconstrictive substance), inhibits the expression of nitric oxide (a vasodilator and platelet inhibitor), and is toxic to macrophages if highly oxidized. As oxidation of biologically active lipids proceeds, other lipids breakdown products of fatty acids and oxysterol are formed, which continue the reaction within the tissue. These events lead to a massive accumulation of cholesterol. The cholesterol-laden macrophages become foam cells; foam cells are the earliest recognized cells of the arterial fatty streak. Oxidized LDL-C provokes an inflammatory response, which is mediated by a number of chemoattractants and cytokines. The process of aging may lead to lipoproteins that are more susceptible to oxidation and have longer resident time in the vascular compartment. Repeated injury and repair within an atherosclerotic plaque eventually leads to fibrous caps protecting the underlying core of lipids, collagen, calcium, and inflammatory cells such as T-lymphocytes. Maintenance of the fibrous plaque is critical to prevent plaque rupture and subsequent coronary thrombosis.[21] An imbalance between plaque synthesis and degradation may lead to a weakened or vulnerable plaque prone to rupture. The fibrous cap may become weakened through the decreased synthesis of the extracellular matrix or increased degradation of the matrix (Fig. 32-5).

FIGURE 32-5

Atherogenesis is initiated by the migration of LDL and remnant lipoprotein particles into the vessel walls. These particles undergo oxidation and are taken up by macrophages in an unregulated fashion, which induces endothelial cell dysfunction. This, in turn, reduces the ability of the endothelium to dilate the artery and cause a prothrombotic state. Unregulated uptake of cholesterol by macrophages leads to foam cell formation, and thus the development of atherosclerotic plaques. Macrophages eventually produce and secrete matric metalloproteinases, which degrade the collagen matrix of the plaques and cause them to be unstable. This can potentially lead to a myocardial infarction. This is a progressive process. (IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; MMP, matrix metalloproteinase; NO, nitric oxide; SR-B1, scavenger receptor class B type 1) *(Reproduced, with permission, from Chisholm-Burns MA, Schwinghammer TL, Malone PM, Kolesar JM, Bookstaver PB, Lee KC, eds. Pharmacotherapy Principles & Practice. 5th ed. New York: McGraw Hill; 2019.)*

Lipoprotein(a) (Lp[a]), a low-density lipoprotein (LDL) variant, containing both apolipoprotein(a) (apo[a]) and apolipoprotein(b) (apo[b]) covalently bound via a disulfide bridge. Lp(a) is an independent risk factor for ASCVD.[22,23] Thought to be elevated in about 20% of the population, the significance of Lp(a) has been utilized to improve ASCVD risk assessment strategies.[22,23] Most recent evidence supports a relationship between elevated Lp(a) levels and both ASCVD and valvular aortic stenosis (VAS) risks, yet the precise pathophysiological mechanism(s) is not completely understood.[22,23]

Theoretically, the pathophysiological mechanisms of Lp(a)-induced ASCVD events include the interaction between oxidized phospholipids and the apo(a) component of Lp(a), resulting in endothelial disruption, lipid deposition, inflammation, and calcification of the vasculature.[22] Apo(a) has structural similarity with plasminogen which may account for its atherogenic properties because it competitively inhibits fibrinolysis and release of plasminogen activator inhibitor-1.[23] This process could further lead to thrombus formation within arterial plaques or turbulent blood flow within stenosis; therefore, causing blockage(s) or embolism in VAS.[22]

While recommendations are still being considered and developed regarding how Lp(a) alters therapy in patients with dyslipidemia, the National Lipid Association (NLA) released a scientific statement in May 2019 detailing recommendations for testing and identifying those at high risk of co-morbidities due to Lp(a) elevations.[23] These recommendations describe screening considerations, potential Lp(a) cut-points when to initiate treatment as well as primary and secondary prevention strategies.[23]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Dyslipidemias

General

- Most patients are asymptomatic for years before they develop ASCVD; the initial presentation may be sudden death due to a CHD event.
- Many patients with dyslipidemia also present with one or more of the following abnormalities:
  - Abdominal obesity
  - Atherogenic dyslipidemia
  - Increased blood pressure
  - Insulin resistance and/or glucose intolerance
  - Prothrombotic or proinflammatory state
- *Patients with three or more of these abnormalities are considered to have the metabolic syndrome

Symptoms of ASCVD

- Chest pain
- Palpitations
- Sweating
- Anxiety
- Shortness of breath
- Loss of consciousness
- Difficulty with speech or movement
- Abdominal pain

Signs

- Abdominal pain
- Pancreatitis
- Eruptive xanthomas
- Peripheral polyneuropathy

Laboratory Tests

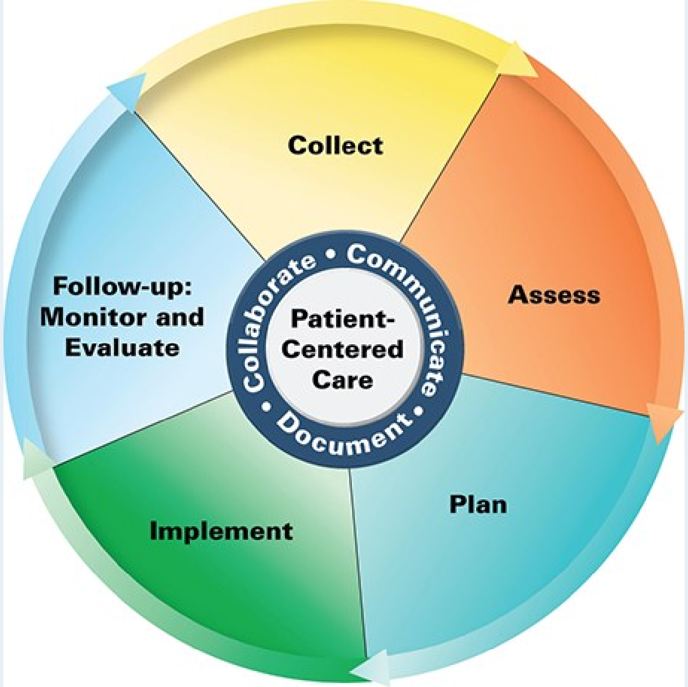
- Elevated total cholesterol, LDL-C, TGs, apolipoprotein B, hsCRP
- Decreased HDL-C

Other Diagnostic Tests

- Screenings for manifestations of vascular disease, including carotid ultrasound, coronary calcium score, ankle-brachial index, and heart catheterization.

PATIENT CARE PROCESS

Patient Care Process for the Management of Dyslipidemias



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, gender, pregnant)
- Patients history: Past medical (eg, HTN), family (eg, early-onset coronary heart disease), social
- Current medications (including over-the-counter [OTC]) and prior lipid-lowering medication use
- Socioeconomic factors that may affect access to treatment or other aspects of care
- Lifestyle assessment: smoking status, exercise, diet, and alcohol intake
- Symptoms indicative of ischemic injury (eg, chest pain)
- Objective data

  - Height, weight, BMI, and blood pressure
  - Lipoprotein concentrations (eg, Total Cholesterol/LDL-C/HDL-C/Triglycerides)
  - Laboratory findings (eg, AST/ALT, urinalysis, TSH, glucose, Serum Creatinine, and BUN at baseline)

Assess

- Potential secondary causes (eg, diabetes mellitus, alcohol abuse, kidney dysfunction, liver disease, drug-induced, thyroid disorder)
- Special needs of specific patient populations such as children/adolescents, pregnant or menopausal women, older adults, ethnic/racial groups, or high-risk conditions/residual risks (eg, patients with rheumatoid arthritis or residual risk despite statin and lifestyle therapy)
- Presence of high-risk comorbid conditions: diabetes mellitus, peripheral arterial disease, coronary artery disease, chronic kidney disease, carotid artery stenosis, and abdominal aortic aneurysm
- Dyslipidemia-related complications (eg, heart disease, stroke)
- Ten-year ASCVD-risk assessment (only if primary prevention)
- Current medications that may contribute to dyslipidemia
- LDL-C reduction based on statin benefit group (see Table 32-5, Figure 32-6, and Figure 32-7)
- Appropriateness and effectiveness of current lipid-lowering therapy (if any)*

Plan

- Tailored therapeutic lifestyle changes (eg, diet and nutrition)
- Drug therapy regimen including specific lipid-lowering medication, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Table 32-5, Figure 32-6, and Figure 32-7). Monitoring parameters including efficacy (eg, lipid panel, cardiovascular events), safety (medication-specific adverse effects), and time frame (3-month initial follow-up intervals, followed by 6 to 12 month intervals once at goal)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy). Self-monitoring of weight, exercise, diet, drug adherence/adverse effects
- Referrals to other providers when appropriate for coordination of care (eg, physician, dietician)*

Implement

- Provide patient education regarding all elements of the treatment plan, including self-management training
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up; consider the time frame to achieve goals of therapy

Follow-up: Monitor and Evaluate

- The occurrence of cardiovascular (CV) events
- Determine patient adherence to treatment plan using multiple sources of information
- Determine response to lipid-lowering therapy and weight-loss goals
- Presence of medication-induced adverse effects (eg, elevated transaminases or myalgia on statins)

Collaborate with patient, caregivers, and other healthcare professionals.

TREATMENT

Desired Outcomes

Desired levels of TC, LDL-C, HDL-C, and TG for adults are provided in Table 32-2. While abnormalities in these surrogate markers may impart an increased risk for ASCVD events, the goal of treatment is to not merely correct lab abnormalities but prevent the development and progression of ASCVD. Thus, the desired outcome is to prevent ASCVD-related morbidity and mortality, including revascularization procedures, MI, and ischemic stroke. Initiation of lipid-lowering therapies primarily involves the use of those agents shown in RCT to reduce ASCVD risk.[17,24]

TABLE 32-2

Classification of Total-, LDL-, HDL-Cholesterol, and Triglycerides in Adults

Total Cholesterol	
<200 mg/dL (5.17 mmol/L) 200-239 mg/dL (5.17-6.20 mmol/L) ≥240 mg/dL (6.21 mmol/L)	Desirable Borderline high High
Low-Density Lipoprotein Cholesterol	
<100 mg/dL (2.59 mmol/L) 100-129 mg/dL (2.59-3.35 mmol/L) 130-159 mg/dL (3.36-4.13 mmol/L) 160-189 mg/dL (4.14-4.90 mmol/L) ≥190 mg/dL (4.91 mmol/L)	Optimal Near or above optimal Borderline high High Very high
High-Density Lipoprotein Cholesterol	
<40 mg/dL (1.03 mmol/L) <50 mg/dL (1.29 mmol/L)	Low (Men) Low (Women)
Triglycerides	
<150 mg/dL (1.70 mmol/L) 150-199 mg/dL (1.70-2.25 mmol/L) 200-499 mg/dL (2.26-5.64 mmol/L) ≥500 mg/dL (5.65 mmol/L)	Normal Borderline high High Very high

General Approach

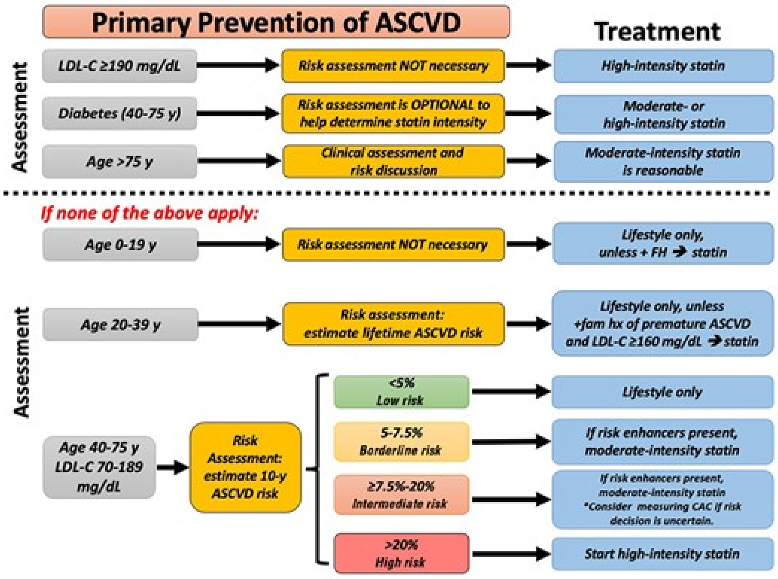
⑥ A comprehensive approach to treating dyslipidemia and all modifiable ASCVD risk factors is required to significantly reduce the risk of first and recurrent CV events. Therapeutic lifestyle change is the first-line therapy for any lipoprotein disorder. A healthy lifestyle should be implemented in all patients with the general components including a reduction in the percent of calories from saturated and *trans* fats, increased intake of soluble fiber, weight reduction if overweight or obese, increased physical activity, and avoiding or quitting tobacco use.[24] Additionally, patients with a diagnosis of hypertension should achieve optimal blood pressure control based on the 2017 ACC/AHA Guidelines for control of hypertension (see Chapter 30, "Hypertension").[25] Persons with diabetes mellitus, especially those with established ASCVD, should receive glucose-lowering therapies that reduce ASCVD risk (see Chapter 94, "Diabetes Mellitus").[26]

⑤ If therapeutic lifestyle changes are insufficient, lipid-lowering agents should be chosen based on which lipid is at an undesirable level and the degree to which it is expected to increase the risk of ASCVD. The decision to initiate lipid-lowering therapy in the management of dyslipidemia should be based on an individual's ASCVD risk and not merely plasma levels of atherogenic lipoproteins (such as LDL-C) alone.[27] Patients with established ASCVD are at the highest risk and most likely to benefit from select lipid-lowering therapies (such as statins). Risk assessment in patients without established ASCVD is more of an art that requires careful consideration of traditional (eg, age, hypertension) and nontraditional (eg, autoimmune diseases, socioeconomic status) risk factors, the risks of lipid-lowering therapy, and patient preference. For patients between 40 and 79 years of age and no history of ASCVD, the ASCVD Risk Estimator Plus (available at: www.tools.acc.org/ascvd-risk-estimator-plus) should be used to facilitate a clinician-patient discussion regarding the benefit and risks of lipid-lowering therapy, especially in patients whose 10-year risk is 7.5% or greater (see Figure 32-6). The Risk Estimator is comprised of the patient's age, gender, race, TC, HDL-C, blood pressure, diabetes status, smoking status, and use of antihypertensives, statins, and aspirin. Importantly, the Risk Estimator is based on data from large population studies of mostly African American and non-Hispanic white men and women. The Risk Estimator can be used for other ethnic groups if they are designated as non- Hispanic white; however, the Risk Estimator will underestimate the risk of American Indians and Asian Americans of South Asian ancestry, while overestimating the risk of Asian Americans of East Asian ancestry and some Hispanics (eg, Mexican Americans).[27] An estimated lifetime risk for ASCVD can also be performed for patients between age 20 and 39, but results should only be used to justify the need for lifestyle changes and not the initiation of lipid-lowering therapy. Additional tools for ASCVD-risk assessment include high-sensitivity C-reactive protein (hsCRP), apolipoprotein B, and lipoprotein(a) [Lp(a)] levels that may be obtained to inform decision making in low-intermediate risk patients or those with recurrent ASCVD events despite appropriate lipid-lowering therapy.[27]

⑥ ⑦ The HMG-CoA reductase inhibitors or "statins" are the drugs of choice for most patients with dyslipidemia.[17] A large body of evidence from randomized, double-blind, placebo-controlled trials has demonstrated the effectiveness of statins on reducing first and recurrent cardiovascular events, cardiovascular mortality, and all-cause mortality.[28] The 2018 ACC/AHA Blood Cholesterol Guideline identified four statin benefit groups where the data from RCT demonstrate clear evidence that the benefit of statin therapy outweighs the potential risks (Figs. 32-6 and 32-7).[17] Nonstatin lipid-lowering therapies (ie, ezetimibe, bempedoic acid, and PCSK9 inhibitors) play a supportive role in the management of dyslipidemia and are primarily used in combination with statins when adequate LDL-C lowering cannot be achieved with statins alone, or in patients unable to tolerate the recommended dose of a statin (Table 32-5).[17]

FIGURE 32-6

The assessment and treatment decision regarding the use of statin therapy for primary prevention is complex and must consider multiple factors. Patient groups with an untreated LDL-C ≥190 mg/dL (4.91 mmol/L) or type 1 or 2 diabetes (age 40-75 years) are eligible for statin therapy without estimating ASCVD risk using the Pooled Cohorts Equation. Given the limited data in adults over age 75, a patient-clinician discussion regarding the benefits and risks of statin therapy for primary prevention is warranted. For all other individuals, age is a primary consideration to determine the appropriate method of risk assessment and treatment recommendations. For conversion of LDL-C levels from units of mg/dL to SI units of mmol/L multiply by 0.02586.



Primary Prevention of ASCVD
Treatment
Assessment
LDL-C ≥190 mg/dL
Risk assessment NOT necessary
High-intensity statin
Diabetes (40-75 y)
Risk assessment is OPTIONAL to help determine statin intensity
Moderate- or high-intensity statin
Age >75 y
Clinical assessment and risk discussion
Moderate-intensity statin is reasonable
If none of the above apply:
Age 0-19 y
Risk assessment NOT necessary
Lifestyle only, unless + FH → statin
Assessment
Age 20-39 y
Risk assessment: estimate lifetime ASCVD risk
Lifestyle only, unless +fam hx of premature ASCVD and LDL-C ≥160 mg/dL → statin
Age 40-75 y LDL-C 70-189 mg/dL
Risk Assessment: estimate 10-y ASCVD risk
<5% Low risk
Lifestyle only
5-7.5% Borderline risk
If risk enhancers present, moderate-intensity statin
≥7.5%-20% Intermediate risk
If risk enhancers present, moderate-intensity statin *Consider measuring CAC if risk decision is uncertain.
>20% High risk
Start high-intensity statin

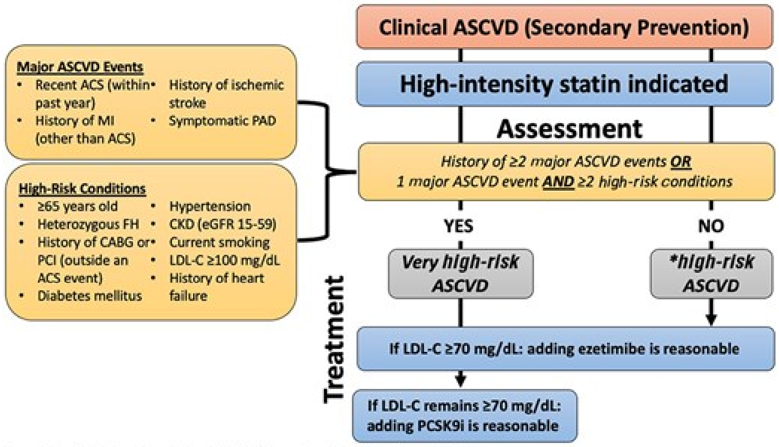
FIGURE 32-7

Patients with established clinical ASCVD are considered secondary prevention and high-intensity statin therapy is automatically indicated. Moderate-intensity statin should only be considered in adults >75 years of age and those unable to tolerate high-intensity statin therapy. After high-intensity statin therapy is initiated, ezetimibe may be added if the LDL-C remains ≥70 mg/dL (1.81 mmol/L). In select, very high-risk patients, adding a PCSK9i is reasonable if the LDL-C remains ≥70 mg/dL (1.81 mmol/L) after adding ezetimibe. For conversion of LDL-C levels from units of mg/dL to SI units of mmol/L multiply by 0.02586.



Clinical ASCVD (Secondary Prevention)
High-intensity statin indicated
Assessment
Major ASCVD Events
• Recent ACS (within past year)
• History of MI (other than ACS)
• History of ischemic stroke
• Symptomatic PAD
High-Risk Conditions
• ≥65 years old
• Heterozygous FH
• History of CABG or PCI (outside an ACS event)
• Diabetes mellitus
• Hypertension
• CKD (eGFR 15-59)
• Current smoking
• LDL-C ≥100 mg/dL
• History of heart failure
History of ≥2 major ASCVD events OR 1 major ASCVD event AND ≥2 high-risk conditions
YES
NO
Very high-risk ASCVD
*high-risk ASCVD
Treatment
If LDL-C ≥70 mg/dL: adding ezetimibe is reasonable
If LDL-C remains ≥70 mg/dL: adding PCSK9i is reasonable

⑧ Numerous clinical outcome trials have been performed to determine whether lipid-lowering therapies reduce ASCVD risk in primary and secondary prevention populations. It is beyond the scope of this chapter, however, to discuss each of these trials in detail. Table 32-3 summarizes select trials supporting the use of statins and select nonstatins (ezetimibe and PCSK9 inhibitors) to reduce ASCVD risk. Most of the primary and secondary prevention studies were double-blinded, randomized, and placebo-controlled, lasting 2 to 7 years, and had sufficient patient numbers to be meaningful. The body of evidence supporting the role of statin therapy to reduce ASCVD is substantial and meta-analysis confirms the first-line role this class of drugs should play in dyslipidemia management.[29] As mentioned previously in this chapter, not all lipid-lowering therapies have translated to reducing ASCVD risk, despite having favorable effects on the lipid profile.

TABLE 32-3

Select Landmark Clinical Trials with Lipid-Lowering Drugs Targeting LDL Cholesterol

Trial	Patient Population (n)	Intervention	Primary Endpoint	Event Rates, Intervention vs Control (%)	RRR (%)	ARR (%)	NNT
Statin Landmark Trials—*Primary prevention*							
AFCAPS/TexCAPS	LDL-C 130-190 mg/dL (3.36-4.91 mmol/L) and HDL-C <47 mg/dL (1.22 mmol/L) (*n*=6,605)	Lovastatin 20-40 mg vs placebo	Acute major coronary events	3.5 vs 5.5	36.4	2.0	50
CARDS	Age 40-75 years with T2DM and LDL-C <160 mg/dL (4.14 mmol/L) plus additional risk factor (*n*=2,383)	Atorvastatin 10 mg vs placebo	Coronary heart disease events, coronary revascularization, or stroke	5.8 vs 9.0	37	3.2	32
JUPITER	LDL-C <130 mg/dL (3.36 mmol/L) and hsCRP ≥2.0 mg/L (*n*=17,802)	Rosuvastatin 20 mg vs placebo	5-point MACE	1.59 vs 2.82	44	1.2	82
HOPE-3	Men and women (age 55 years and older) with at least one cardiovascular risk factor (*n*=12,705)	Rosuvastatin 10 mg vs placebo	3-point MACE	3.7 vs 4.8	24	1.1	91
Statin Landmark Trials—*Secondary prevention*							
HPS	Previous ASCVD or high risk (*n*=20,536)	Simvastatin 40 mg vs placebo	All-cause mortality	12.9 vs 14.7	13	1.8	56
PROSPER	Elderly (age 70-82 years) with previous vascular disease or elevated risk (*n*=5,804)	Pravastatin 40 mg vs placebo	3-point MACE	14.1 vs 16.2	15	2.1	48
TNT	Clinical coronary heart disease (*n*=10,001)	Atorvastatin 80 mg vs 10 mg	4-point MACE	8.7 vs 10.9	22	2.2	45
Non-statin Landmark Trials							
IMPROVE-IT	Recent ACS (*n*=18,144)	Ezetimibe + simvastatin vs simvastatin	5-point MACE	32.7 vs 34.7	6	2	50
FOURIER	Previous ASCVD (*n*=27,564)	Evolocumab + statin vs statin	5-point MACE	9.8 vs 11.3	15	1.5	67
ODYSSEY-OUTCOMES	Recent ACS (*n*=18,924)	Alirocumab + statin vs statin	4-point MACE	9.5 vs 11.1	15	1.6	63

ACS, acute coronary syndrome; ARR, absolute risk reduction; AFCAPS/TexCAPS, Air Force/Texas Coronary Atherosclerosis Prevention Study[30]; ASCVD, atherosclerotic cardiovascular disease; CARDS, Collaborative Atorvastatin Diabetes Study[12]; FOURIER, Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Patients with Elevated Risk[31]; HOPE-3, Heart Outcomes Prevention Evaluation 3[32]; HPS, Heart Protection Study[34]; hsCRP, high-sensitivity C-reactive protein; IMPROVE-IT, Improved Reduction of Outcomes: Vytorin Efficacy International Trail[35]; JUPITER, Justification for the Use of Statins in Prevention[36]; LDL-C, Low-Density Lipoprotein Cholesterol; MACE, Major Adverse Cardiovascular Events; MI, myocardial infarction; NNT, Number Needed to Treat; ODYSSEY-OUTCOMES, Evaluation of Cardiovascular Outcomes After an Acute Coronary Syndrome During Treatment With Alirocumab[73]; PROSPER, Pravastatin in elderly individuals at risk of vascular disease[37]; RRR, relative risk reduction; T2DM= Type 2 Diabetes Mellitus; TNT, Treat to New Targets Trial[38]; 3-point MACE= cardiovascular death, nonfatal myocardial infarctions, nonfatal stroke.

4-point MACE= death from coronary heart disease, nonfatal MI, fatal or nonfatal stroke, hospitalization for unstable angina

5-point MACE= cardiovascular death, nonfatal myocardial infarctions, nonfatal stroke, arterial revascularization, hospitalization for unstable angina.

Nonpharmacologic Therapy

Lifestyle modification is the cornerstone of ASCVD-risk reduction and is recommended in all patients, including those receiving lipid-lowering therapy. Weight and body mass index (BMI) should be determined at each visit and lifestyle patterns to induce a weight loss of 5% to 10% should be discussed in persons who are overweight or obese (Table 32-4). Moderate-to-vigorous intensity physical activity is recommended three to four times per week with each session lasting 40 minutes on average. All patients should also be counseled to stop smoking and avoid tobacco products altogether.[24]

TABLE 32-4

Nonpharmacologic Therapy to Improve Lipid Levels and ASCVD Risk

Recommendations to Modify Select Lipid Parameters	
Lower LDL cholesterol	● Increase soluble fiber intake ● Phytosterol (2g/day) supplementation
Increase HDL cholesterol	● Increase physical activity ● Smoking cessation
Lower triglycerides	● Lose weight (5%-10% body weight loss) ● Increase physical activity ● Abstain from alcohol ● Reduce intake of refined carbohydrates and sugars
Recommendations to Reduce ASCVD Risk	
Nutrition and diet	● Avoid eating trans fats ● Increase intake of vegetables, fruits, legumes, nuts, whole grains, and fish ● Replace foods containing saturated fats with unsaturated (monounsaturated and polyunsaturated) fats ● Minimize intake of processed meat products, refined carbohydrate foods, and sweetened beverages ● Reduce intake of cholesterol and sodium-containing foods ● For patients who are overweight or obese, reduce daily calories to achieve and maintain weight loss of 5%-10%
Physical activity	● Obtain at least 150 min/week of moderate-intensity or 75 minutes of vigorous-intensity physical activity ● Decrease sedentary behaviors
Other lifestyle factors	● Smoking cessation and avoiding tobacco products ● Avoid secondhand smoke exposure

ASCVD, atherosclerotic cardiovascular disease.

It is important to recognize that there is no single diet suitable for every patient. Instead, advise patients to reduce the percent of calories from saturated and *trans* fats by following a dietary pattern that emphasizes vegetables, fruits, whole grains, low-fat dairy, poultry, fish, legumes, and nuts; while limiting the intake of sweets, sugary beverages, and red meat. Plans that closely mirror this dietary pattern and effectively lower LDL-C include DASH, the USDA Food Pattern, and AHA Diet. Although the Mediterranean- style diet has no consistent effect on LDL-C levels, it reduces major cardiovascular events among persons at high cardiovascular risk when compared to a control diet. Any recommended dietary pattern should be adapted to a patient's caloric requirements, cultural food preferences, and other medical conditions (eg, diabetes mellitus). Individualized diet counseling that provides acceptable substitutions for unhealthy foods and ongoing reinforcement by a registered dietitian are necessary for maximal effect. It is also important to involve all family members, especially if the patient is not the primary person preparing food.[24]

Less than one-third of Americans meet the 2015-2020 Dietary Guidelines for Americans limit of less than 10% of calories from saturated fats.[39] In patients with lipid disorders, the 2013 AHA/ACC Lifestyle Management Guideline recommended only 5% to 6% of total calories from saturated fat.[24] This can be achieved by recommending patients limit or avoid fast food, high-fat dairy products, and sweets. Previous dietary guideline recommendations to limit dietary cholesterol to 300 mg/day was omitted in 2015. However, it is still recommended that individuals limit their daily dietary cholesterol intake. A dietary pattern low in saturated and *trans* fats will typically result in a reduction in dietary cholesterol since foods high in saturated and *trans* fats are often high in cholesterol. A 12-week trial of lifestyle modification is generally recommended before considering lipid-lowering therapy in patients without evidence of ASCVD, diabetes, or other high-risk features. Importantly, lifestyle modification alone is inappropriate for patients with established ASCVD or diabetes given the benefit of statins in these high-risk patients.

Dietary Supplements

Select dietary supplements may be useful to augment diet and lipid-lowering therapy. Increased intake of soluble fiber in the form of oat bran, pectins, certain gums, and psyllium products can reduce total and LDL- C, but have little or no effect on HDL-C or TG levels. Soluble fiber binds cholesterol and bile acids in the small intestine, which decreases absorption and reabsorption. Total daily fiber intake should be about 25 g/day, yet most Americans average only half of the recommended amount.[40] Dietary supplements containing fiber may be used to supplement the diet and achieve the recommended daily intake. An intake of 3 to 12 g/day show reductions in total and LDL-C of 10 mg/dL (0.26 mmol/L) and 12 mg/dL (0.31 mmol/L), respectively, compared to control.[27] It remains unknown if soluble fiber supplements have any impact on cardiovascular morbidity and mortality. Although seemingly safe, patients should be advised to stay well hydrated to avoid gastrointestinal distress. These products may also be useful in managing constipation associated with the bile acid sequestrants (BASs).

In epidemiologic studies, ingestion of large amounts of oily, cold-water fish (such as salmon) is associated with a reduction in ASCVD risk. Modest consumption (1-2 servings per week) reduces the risk of cardiovascular death and total mortality.[41] The American Heart Association recommends eating oily fish at least twice a week; however, there are concerns with some types of fish (such as tuna) that often have high levels of environmental contaminants. There are also concerns about environmental sustainability. Fish oil supplementation is an alternative option that provides a consistent daily intake of omega-3 PUFA such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Fish oil supplementation significantly reduces TG levels and VLDL-C but may increase total cholesterol and LDL-C. Other potentially favorable cardiovascular effects of fish oil supplementation include antiarrhythmic, antiplatelet, and anti-inflammatory properties. Despite this, a meta-analysis of 10 RCTs found low doses (less than 2 g/day) of omega-3 PUFA supplementation did not reduce the risk of ASCVD events.[42] Low-dose omega-3 PUFA supplementation is not recommended in primary prevention patients, especially those with diabetes who do not have established ASCVD.[43,44] Additional details regarding prescription omega-3 PUFA products are further discussed under drug therapy.

Phytosterols, including plant sterols and stanols isolated from vegetable oils, also reduce LDL-C levels. Ingestion of 2 g/day will reduce LDL-C by 5% to 15%, while doses above 3 g/day confer no additional LDL-C lowering.[27] The efficacy of plant sterols and plant stanols is comparable. The mechanism by which phytosterols reduce LDL-C remains unclear but may decrease the transport of cholesterol in the intestinal brush border membrane and affect cholesterol uptake via Niemann-Pick C1-Like 1 (NPC1L1) and other transporters. Because lipids are needed to solubilize stanol/sterol esters, they are usually available in commercial butter-like spreads (such as Benecol®). The presence of plant stanols/sterols is listed on the food label. Phytosterols should be administered 2 to 4 hours before or after BASs to avoid the binding of phytosterols in the gut. Although phytosterols are generally recognized as safe (GRAS) in the United States, they can cause gastrointestinal distress and should be avoided in patients with sitosterolemia, a rare genetic disorder characterized by a 50- to 100-fold increase in plant sterol levels and rapid onset of atherosclerosis.[45] The effects of long-term phytosterol supplementation on ASCVD risk remains unknown.

Red yeast rice is a commonly used dietary supplement in the United States that originates from Chinese medicine. The active ingredient of red yeast rice is monacolin K, which is chemically identical to lovastatin. This leads some patients to believe red yeast rice is a “natural” statin and, therefore, safer than statins available only by prescription; however, the active ingredient in over-the-counter (OTC) red yeast rice products vary by over 120-fold. Many products contain little to no monacolin.[46] Conversely, case reports of rhabdomyolysis, liver toxicity, and renal failure have raised concerns about some red yeast rice formulations containing significantly higher levels of monacolin K than described on the label.[47] Red yeast rice is not recommended as a suitable alternative to statins. However, if patients choose to take red yeast rice, it is recommended that they purchase it from a reputable supplier and avoid concurrent use with prescription statins.

Pharmacologic Therapy

9 There are numerous randomized, double-blinded clinical trials demonstrating that reduction of LDL-C reduces ASCVD-event rates in the setting of

primary and secondary prevention.[29] Epidemiological studies suggest that every 38 mg/dL (0.98 mmol/L) reduction in LDL-C produces a 21% reduction in ASCVD event rates over 5 years.[48] Additional findings from large prospective cohort studies and Mendelian randomization studies have also demonstrated a dose-dependent log-linear association between LDL-C and ASCVD risk[49] and that lower levels of LDL-C achieve significant reductions in ASCVD risk. These studies provide a strong rationale for attempting to lower plasma cholesterol and LDL-C in patients at risk for ASCVD.[49] It should be noted, however, that not all lipid-lowering agents that reduce LDL-C have resulted in a reduction in ASCVD events (eg, CETP inhibitors). Thus, LDL-C lowering alone should not be the sole basis for selecting an appropriate agent.[17,27] Lipid-lowering drugs can be broadly divided into agents that primarily decrease atherogenic cholesterol-containing lipoprotein particles (such as statins) and those that primarily decrease TG levels (such as fibrates).

Treatment of Specific Dyslipidemia Subtypes

Familial Hypercholesterolemia

Individuals with familial hypercholesterolemia (FH) have a high lifetime risk of developing ASCVD. Compared to the general population, FH is associated with a 24-fold higher risk of developing acute MI before the age of 40 years.[50] FH should be suspected in adults with untreated LDL-C levels of 190 mg/dL (4.91 mmol/L) or greater or non-HDL cholesterol levels of 220 mg/dL (5.69 mmol/L) or greater who have a family history of high cholesterol or ASCVD in first-degree relatives. Physical findings (such as xanthomas or corneal arcus) may be present in some patients with FH, but their absence does not rule out a diagnosis of FH. In clinical practice, one of several validated tools, including the Dutch Lipid Clinic Network, US Make Early Diagnosis Prevent Early Death (MEDPED), and Simon-Broome Registry, are used to make a formal diagnosis of FH. Genetic testing is available, however, approximately 20% of patients with clinically definite FH will not have an identifiable mutation; therefore, a negative genetic test does not exclude FH.[51] Importantly, cascade screening of all first-degree relatives of diagnosed FH patients is highly recommended as an effective strategy to identify previously undiagnosed FH patients.

Intensive lifestyle and pharmacological therapy are often necessary for adults with FH. In patients with FH who have not had an ASCVD event, a high-intensity statin is warranted and those with an LDL-C ≥100 mg/dL (2.59 mmol/L) despite max tolerated statin should receive ezetimibe, bempedoic acid, and/or a PCSK9 inhibitor. The LDL-C threshold to consider non-statin therapies in patients with FH and a history of ASCVD, however, is ≥70 mg/dL (1.81 mmol/L).

⑩ Mipomersen and lomitapide are orphan drugs indicated for use in patients with HoFH and reduce LDL- C levels by ~25% and ~40%, respectively.[52] Mipomersen is an oligonucleotide inhibitor of apolipoprotein B-100 synthesis administered via subcutaneous injection, while the orally administered lomitapide is a microsomal triglyceride transfer protein, or microsomal TG transfer protein inhibitor, which reduces the level of cholesterol that the liver and intestines assemble and secrete into the circulation. Mipomersen is associated with injection site pain and reactions, while both mipomersen and lomitapide have a black box warning for severe hepatotoxicity and are only available through restricted Risk Evaluation and Mitigation Strategy (REMS) programs.[52] Other treatment options for HoFH patients include LDL apheresis (a process similar to dialysis that removes LDL from the blood) and liver transplant.[50]

Evinacumab was approved to lower LDL-C in patients with HoFH at the age of 12 years and older. Evanicumab is a humanized monoclonal antibody that inhibits angiopoietin-like 3 (ANGPTL3) protein and is administered as an IV infusion every 4 weeks. The ANGPTL3 protein regulates lipid metabolism by inhibiting LPL and endothelial lipase enzymes. Inhibition of ANGPTL3 with Evinacumab reduces LDL-C by ~50% and also reduces TG by ~55% in patients with HoFH.[53] Adverse effects of Evinacumab include infusion-site reactions, influenza-like illness, and rhinorrhea. It is unknown whether evinacumab reduces ASCVD events.

Hypertriglyceridemia

Elevated TG levels are strongly associated with an increased risk of ASCVD; however, the direct role of TG in the development of ASCVD is debated.[54] All patients with elevated TG levels (see Table 32-2) should be advised to implement lifestyle interventions that reduce TG levels, including a 5% to 10% reduction in body weight, reducing consumption of sugar and refined carbohydrates, increasing physical activity, smoking cessation, and restricting alcohol. Secondary causes of hypertriglyceridemia should also be identified and addressed. Uncontrolled diabetes and chronic kidney disease are common causes of elevated TG levels, along with certain medications (such as protease inhibitors and atypical antipsychotics). The best approach to managing patients whose TG levels remain elevated after optimizing lifestyle interventions and addressing secondary causes remains unclear, but statins are generally considered first-line given they can reduce TG levels by up to 30% at higher doses and help achieve desired levels of LDL-C.[55] Fibrates effectively lower TG levels but are not routinely used for borderline-high TG levels as there is no evidence supporting their use to reduce ASCVD risk. Omega-3 PUFA also significantly lower TG levels at higher doses (2-4 g/d) but only icosapent ethyl (EPA-only) prescription product is indicated for borderline-high TG levels and to reduce ASCVD risk.[56]

Fasting TG levels exceeding 500 mg/dL (5.65 mmol/L) are more commonly associated with pancreatitis and other consequences of hyperchylomicronemia (such as eruptive xanthomas). At this level of elevated TG, a genetic form of hypertriglyceridemia often coexists with other causes of elevated triglycerides such as diabetes. Dietary fat restriction is a basic element of treatment as this reduces the synthesis and entry of additional chylomicrons into the circulation. Lipid-lowering therapies that primarily lower TG levels (ie,fibrates and omega-3 PUFA) are recommended as first-line agents.[56] Statins may be reasonable first-line options in those patients with an ASCVD risk of 7.5% or greater. If TG levels are persistently over 500 mg/dL (5.65 mmol/L), it is reasonable to consider adding omega-3 PUFA or fibrate therapy. Success in treatment is defined as a reduction in triglycerides below 500 mg/dL (5.65 mmol/L) and preventing pancreatitis.

Low HDL Cholesterol

Low HDL-C is a strong independent risk predictor of ASCVD5.[7] Low HDL-C is defined as less than 40 mg/dL (1.03 mmol/L) for men and less than 50 mg/dL (1.29 mmol/L) for women, but there is no specified goal for HDL-C raising. Low HDL-C may be a consequence of insulin resistance, physical inactivity, diabetes, cigarette smoking, high carbohydrate intake, and certain drugs. In patients with low HDL-C levels, the primary target remains LDL-C. Niacin has the potential for the greatest increase in HDL-C compared to other lipid-lowering therapies and the effect is more pronounced with regular or immediate-release forms than with sustained-release forms. However, no RCT has resulted in a reduction in ASCVD risk by increasing HDL-C5.[8,59] Additionally, several CETP inhibitors capable of raising HDL-C levels as much as 135% were evaluated in randomized, placebo-controlled trials but no additional benefit was found when these drugs were added to background statin therapy.[57] Due to the lack of pharmacological agents demonstrating an improvement in clinical outcomes by focusing on raising HDL-C, lifestyle modification (such as smoking cessation and increasing physical activity) remains the preferred approach. Although alcohol consumption increases HDL-C, it is not acceptable to recommend this to patients who do not already consume alcohol.

Medications that Primarily Lower Atherogenic Cholesterol

HMG-CoA Reductase Inhibitors (Statins)

Statins (such as atorvastatin) are considered the first-line lipid-lowering therapies for managing dyslipidemia due to robust evidence from multiple RCTs demonstrating that statins significantly decrease the risk of first (primary prevention) and recurrent (secondary prevention) cardiovascular events.[17,48] Statins significantly reduce LDL-C levels (20%-60%), modestly increase HDL-C (6%-12%), and decrease TG levels (10%- 29%).[60] Statins interrupt the conversion of HMG-CoA to mevalonate, the rate-limiting step in de novo cholesterol biosynthesis, by inhibiting HMG-CoA reductase (see Fig. 32-4). Metabolic studies with statins in normal volunteers and patients with hypercholesterolemia suggest a reduced synthesis of LDL-C, as well as enhanced catabolism of LDL mediated through LDL receptors, as the principal mechanisms for lipid-lowering effects. Statin selection is primarily based on the patient's individual ASCVD risk and indicated intensity (see Table 32-5). Currently available products in order of decreasing LDL-C lowering potency, include rosuvastatin, atorvastatin, pitavastatin, simvastatin, lovastatin, pravastatin, and fluvastatin.[60] The plasma half-lives for all the statins are relatively short (1-3 hours) except for atorvastatin, pitavastatin, and rosuvastatin, which may account for their potency.[60] Statins are generally well tolerated but are not without adverse effects. However, discontinuation rates due to adverse effects in randomized, double-blind, placebo-controlled trials have often been similar between statin and placebo.[61]

TABLE 32-5

Intensity of Statin Therapy by Drug and Daily Dose

High-Intensity Statin Therapy	**Moderate-Intensity Statin Therapy**	**Low-Intensity Statin Therapy**
Lowers LDL-C on average by ≥50%	Lowers LDL-C on average by 30% to <50%	Lowers LDL-C on average by <30%
Atorvastatin 40-80 mg **Rosuvastatin 20-40 mg**	**Atorvastatin 10-20 mg** **Rosuvastatin 5-10 mg** **Simvastatin 20-40 mg**[a] Pravastatin 40-80 mg **Lovastatin 40 mg** Fluvastatin XL 80 mg **Fluvastatin 40 mg BID** Pitavastatin 2-4 mg	Simvastatin 10 mg **Pravastatin 10-20 mg** **Lovastatin 20 mg** Fluvastatin 20-40 mg Pitavastatin 1 mg

[a] Simvastatin is not recommended by the FDA to be initiated at 80 mg/day due to increased risk of myopathy and rarely rhabdomyolysis.

FDA, Food and Drug Administration; RCT, Randomized clinical trials.

Boldface type indicates medications that have cardiovascular outcome data from RCTs when given in the specified dose.

Statin-associated muscle symptoms (SAMS) are reported by 10% to 25% of statin users and are frequently reported by patients as a reason for statin discontinuation.[62] While various definitions of SAMS exist, the clinical diagnosis of SAMS is based on a subjective clinical assessment. Myalgia is the most reported muscle-related adverse effect with statin therapy and refers to bilateral muscle achiness, weakness, or cramps affecting larger muscle groups (such as thighs and back). Myopathy is often used interchangeably with myalgia, but myopathy is a general term used for any muscle-related symptoms. The most concerning of SAMS is rhabdomyolysis, which is a rapid breakdown of skeletal muscle resulting in creatine kinase (CK) elevations greater than 10 times the upper limit of normal. The release of myoglobin from damaged muscle tissue may also compromise renal function and lead to acute kidney injury. Patients presenting with rhabdomyolysis will often describe their urine as dark or "tea-colored" and present with nausea, vomiting, confusion, coma, cardiac arrhythmias, electrolyte disturbances, and even death. Fortunately, rhabdomyolysis in statin-treated patients is exceedingly rare occurring in only 0.1% of patients in RCT compared to 0.04% of patients receiving placebo. Rhabdomyolysis is not only caused by statins but can also be induced by extreme physical exercise, certain metabolism disorders (eg, diabetic ketoacidosis), other drugs (eg, colchicine), toxins, and infection.

Certain risk factors are known to increase the risk of developing SAMS and recognition of these risk factors at the time of statin initiation may minimize the risk of SAMS. Known risk factors include advanced age, female gender, low body mass index, frequent heavy exercisers, comorbidities (eg, kidney disease, hypothyroidism), and increased serum statin concentrations due to drug-drug interactions.[62] A lower dose might be necessary for patients with multiple risk factors for SAMS, and once the starting dose is tolerated, the dose can be titrated to the desired potency. Avoiding major drug-drug interactions is a significant modifiable risk factor for SAMS that pharmacists can directly impact. Nearly 80% of all medications are metabolized in the liver by the cytochrome P450 system (CYP) with CYP3A4 being the most predominant.[63] Statins are no different as nearly all statins, except pravastatin, are metabolized to some degree by CYP isoenzymes. Lovastatin, simvastatin, and atorvastatin are associated with more significant drug-drug interactions since they are predominantly metabolized by CYP3A4, while fluvastatin, pitavastatin, and rosuvastatin rely on other CYP isoenzymes (eg, CYP2C9, CYP2C8, CYP2C19).[64]

The co-prescribing of medications that compete with or inhibit the same CYP isoenzyme (ie, verapamil) can increase serum statin concentrations and the risk for SAMS. The concurrent use of medications such as gemfibrozil that interfere with statin glucuronidation, which is responsible for statin clearance, increases the risk of SAMS.

The management of SAMS requires a multifaceted approach. Documentation of the patients' reported symptoms and determining the probability of

SAMS is an important first step. A Statin Intolerance App (available at: http://www.acc.org/statinintoleranceapp) created by the ACC is a helpful resource that can be used to determine the possibility of SAMS and provide guidance on managing patients with possible SAMS. Statin therapy should be generally discontinued in patients with intolerable symptoms. If symptoms resolve, initiate a different statin at a lower dose.[62,65] Additionally, hydrophilic statins (such as rosuvastatin) may be better tolerated than lipophilic statins (such as simvastatin). In patients where symptoms do not improve, other potential causes of muscle pain should be excluded, including hypothyroidism and vitamin D deficiency, before a statin rechallenge.[65] Alternative dosing strategies (eg, every other day) using statins with long half-lives (atorvastatin, rosuvastatin, and likely pitavastatin) may also be considered. Nonstatin therapies may be considered in patients who fail multiple statins. While routine CK monitoring is not recommended, a CK measurement prompted by patient symptoms can be used to exclude rhabdomyolysis and can assist with identifying those with definite myalgia. Importantly, patients should be reassured that statins are effective and safe, and SAMS is reversible with statin discontinuation.

Other notable adverse effects of statins include mild elevations in serum transaminase levels (primarily alanine aminotransferase [ALT]). Liver enzymes are not, however, an accurate measure of liver function and there is no causal relationship between statin use and liver failure. Therefore, routine periodic monitoring of liver enzymes is not required, but liver enzyme tests should be obtained before starting statin therapy to have a baseline value for comparison if liver enzymes are later discovered to be elevated. Other potential causes for elevated liver enzymes, including excessive alcohol intake, infection, and select medications should also be evaluated. Statins may be initiated in patients with chronic liver disease, compensated cirrhosis, and nonalcoholic fatty liver disease; however, statins are contraindicated in patients with decompensated cirrhosis or acute liver failure.[65]

Statin use is also associated with a small increased risk of new-onset diabetes.[62] This was first observed in the JUPITER (Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin) trial, where the number of new-onset diabetes cases was 0.6% higher in those receiving rosuvastatin 20 mg/day compared to placebo.[36] Subsequent meta-analyses of statin trials have also found a modest increase in the number of new-onset diabetes cases among statin-treated patients compared to placebo, but the absolute risk increase is <1%.[66,67] Common attributes of statin users who develop new-onset diabetes include receiving higher doses of statins and having other risk factors for diabetes, including obesity, impaired fasting glucose, HbA1c >6% (0.06; 42 mmol/mol), or metabolic syndrome.[68] Mechanisms to explain the association between statin use and new-onset diabetes remain unclear. However, observational data suggest that higher cholesterol levels are protective against developing diabetes. This may be attributable to changes at the cellular level involving disruption of cholesterol-sensitive cellular functions that affect insulin secretion and insulin sensitivity.[62] Ultimately, the benefit of statin therapy greatly outweighs the risk of new-onset diabetes as statin use in patients at high ASCVD risk will prevent approximately three ASCVD events for every new case of diabetes. Table 32-6 lists common adverse effects of available lipid-lowering therapies.

TABLE 32-6

Safety of Lipid-Lowering Therapies

Lipid-Lowering Drug Class	**Adverse Effects**		**Contraindications**
	Common/possible (1%- 10%)	Rare/unlikely (<1%)	
Statins	• Statin associated muscle symptoms (myalgia/myopathy) • New-onset diabetes mellitus • Transient, mild elevation in transaminase levels	• Rhabdomyolysis • Severe hepatotoxicity	• Pregnancy/breastfeeding • Decompensated cirrhosis • Acute liver failure
Cholesterol absorption inhibitors	• GI adverse effects • Myalgias (when used with statin) • Elevated transaminase levels (when used with statin)	• Thrombocytopenia	• Pregnancy/breastfeeding • Acute liver failure

Bile acid sequestrants	- GI adverse effects and/or obstruction - Impaired absorption of fat-soluble vitamins - Reduced bioavailability of select drugs	- Ileus - Cholecystitis - Severe hypertriglyceridemia	- History of bowel obstruction - Fasting TG are 300 mg/dL or higher
ACL inhibitors	- Hyperuricemia	- Increased risk of tendon rupture - Increased risk of benign prostate hyperplasia	
PCSK9 mAbs	- Injection-site reactions - Flu-like symptoms post-injection		- Hypersensitivity reaction to alirocumab or evolocumab
Fibrates	- GI adverse effects - Transient elevation in transaminases - Myalgias (especially when used with statin) - Mild increase in serum creatinine	- Increased risk of gallstones	- Pre-existing gallbladder disease - CrCl of 30 mL/min (0.5 mL/s) or lower
Omega-3 PUFA	- GI adverse effects - Eructation - Increased risk of bleeding when used with antiplatelets or anticoagulants - Increased risk of atrial fibrillation or flutter		- Caution in patients with allergy or sensitivity to fish and/or shellfish
Niacin	- Dermatologic effects (flushing/itching) - Increased transaminases - Hyperuricemia - Hyperglycemia	- Increased risk of atrial fibrillation or flutter - Rhabdomyolysis (with statin) - Hepatotoxicity (with statin)	- Active peptic ulcer - Arterial hemorrhage - Persistently elevated transaminase levels
Inclisiran	- Injection-site reactions		- Pregnancy/breastfeeding
Evinacumab	- Infusion-site pruritus - Influenza-like reactions - Rhinorrhea		- Pregnancy/breastfeeding

ACL, Adenosine Triphosphate-citrate Lyase; CrCl, Creatinine Clearance; mAbs, monoclonal antibodies; PUFA, Polyunsaturated Fatty Acids; SAMS, Statin-associated Muscle Symptoms.

Cholesterol Absorption Inhibitors

Ezetimibe is a preferred adjunct therapy given, it modestly reduces the risk of recurrent cardiovascular events in a secondary prevention population when used in combination with statin therapy.[35] The primary lipid-lowering effect of ezetimibe is a modest reduction in LDL-C of 15% to 24%; with higher reductions achievable when used in combination with statin therapy.[35,69] Ezetimibe reduces LDL-C by inhibiting the NPC1L1 protein, an important transporter of cholesterol absorption in the small intestine and hepatocytes.[69] Known polymorphisms of *NPC1L1* are associated with lower LDL-C levels and decreased ASCVD risk; thus, providing a rationale why ezetimibe reduces ASCVD risk.[70] Other than mild gastrointestinal complaints (ie, diarrhea) and post-marketing reports of myalgia and mild ALT elevations when used in combination with statins, ezetimibe is generally well tolerated. Previous concerns over a potential increased risk of cancer have been nullified given recent prospective clinical trial data showing there is no increased risk of cancer with ezetimibe use.[35] Ezetimibe has no effects on the CYP450 enzyme system; however, concomitant use with cyclosporine can lead to increased exposure to both ezetimibe and cyclosporine.[69]

The BASs, such as colesevelam, modestly reduce LDL-C (13%-20%) and reduce cardiovascular events when used as monotherapy.[71] There is no data to determine if the benefits observed with BAS monotherapy translates to its use in combination with statin therapy. As such, BAS are generally used as adjunct therapy with statins when desired LDL-C levels are not achieved with statins alone. Importantly, BAS are considered first line during pregnancy since they are not systemically absorbed and pose no risk to the fetus. The primary action of BAS is to bind bile acids in the intestinal lumen, with a concurrent interruption of enterohepatic circulation of bile acids and a markedly increased excretion of acidic steroids in the feces. This decreases the bile acid pool size and stimulates the hepatic synthesis of bile acids from cholesterol. Depletion of the hepatic pool of cholesterol results in an increase in cholesterol biosynthesis and an increase in the number of LDL-R on the hepatocyte membrane. The increased number of receptors stimulates an enhanced rate of catabolism from plasma and lowers LDL-C levels. The increase in hepatic cholesterol biosynthesis may be paralleled by increased hepatic VLDL production and, consequently, BAS may aggravate hypertriglyceridemia and should be avoided in those with TG levels exceeding 300 mg/dL (3.39 mmol/L).[33]

One of the main barriers to BAS is their poor tolerability profile. Early BAS (such as cholestyramine) were developed as powders that require mixing with water or juice to create a slurry for oral administration. Gastrointestinal complaints of constipation, bloating, epigastric fullness, nausea, and flatulence are commonly reported with these formulations.[33] These adverse effects can be minimized by increasing fluid intake, modifying the diet to increase bulk, and using stool softeners. Tablet forms of BAS (ie, colesevelam) are generally better tolerated than resin powders and associated with lower overall discontinuation rates.[72] Other potential adverse effects include impaired absorption of fat-soluble vitamins A, D, E, and K; gastrointestinal obstruction; and reduced bioavailability of other drugs such as warfarin, levothyroxine, and phenytoin.[33] Drug-drug interactions may be avoided by taking other medications 1 hour before or 4 hours after the BAS.[33] Colesevelam is not only approved as a lipid-lowering agent but also as an antihyperglycemic that modestly lowers glucose levels in patients with type 2 diabetes mellitus.[73] Given the better safety and tolerability profile of ezetimibe, BAS should be reserved only for those patients unable to tolerate ezetimibe who need additional LDL-C lowering despite maximally tolerated statin therapy.[33]

Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Modulating Therapies

Inhibition of PCSK9 reduces LDL-C by as much as 60% when added to background statin therapy. Reducing PCSK9 levels promotes LDL-R recycling to the cell surface, which increases LDL-C clearance from the circulation. Both alirocumab and evolocumab are fully human monoclonal antibodies to PCSK9 and were approved by the FDA in 2015.[31] Randomized, double-blind clinical trials have also shown that these agents effectively reduce recurrent cardiovascular events in patients following an acute coronary event and secondary prevention populations when added to background statin therapy.[31,74] Alirocumab and evolocumab are both administered by subcutaneous injection. Although this may be a barrier for some patients, PCSK9 inhibitors can be administered bi-weekly or once-monthly. The most common adverse effect reported are injection site reactions, which can be minimized by allowing the injection to come to room temperature before use and icing the site before injecting. Some patients may also report "flu-like" symptoms after the injection. There were initial concerns over a potential increased risk for neurocognitive adverse effects; however, a randomized trial found no difference in cognitive function between those randomized to evolocumab *versus* placebo over 19 months of follow-up.[75] Furthermore, those patients who reach low levels of LDL-C (less than 20 mg/dL [0.52 mmol/L]) do not appear to be an increased risk of adverse events.[76] Despite this favorable data, the long-term effects of achieving low levels of LDL-C with PCSK9 inhibitors remain unknown. Despite their LDL-C lowering potency and favorable safety profile, PCSK9 inhibitors frequently require a prior authorization due to their higher cost compared to other LDL-C lowering therapies. Although PCSK9 inhibitors should primarily be used in combination with maximally tolerated statins in high-risk patients unable to achieve desired LDL-C levels with a statin alone, alirocumab and evolocumab are FDA-approved for use as monotherapy in patients with primary hyperlipidemia (ie, heterozygous familial hypercholesterolemia).[31,74]

Inclisiran is a small interfering RNA (siRNA) molecule that reduces the production of PCSK9 by inhibiting messenger RNA.[77] This novel biological agent has a sustained effect on LDL-lowering and is given subcutaneously every 3 to 6 months. In Phase 3 clinical trials, inclisiran reduced LDL-C by an average of 50% when given as add-on therapy in patients who were treated with a high-intensity statin but had not achieved their LDL-C goal. Inclisiran is approved as an additional treatment to maximally tolerated statin therapy to further lower LDL-C in adults with HeFH or ASCVD. The most common adverse effects reported are injection-site reactions, which are generally transient and mild. Whether Inclisiran lowers cardiovascular event rates is currently being investigated in the ORION-4 trial (NCT03705234).

Adenosine Triphosphate-Citrate Lyase Inhibitors

Adenosine triphosphate-citrate lyase (ACL) is a cytoplasmic enzyme responsible for generating acetyl coenzyme A which is needed during the de novo synthesis of fatty acids and cholesterol. ACL inhibitors prevent cholesterol production upstream from HMG CoA reductase inhibitors (ie, statins) and the two therapeutic strategies can be used in combination. Bempedoic acid is an orally administered ACL inhibitor that provides additional LDL-C lowering. In Phase 3 clinical trials, bempedoic acid produced modest reductions in LDL-C (15%-20%) when combined with statin therapy or used as monotherapy in patients who are unable to tolerate statins.[77] It can also be combined with a cholesterol absorption inhibitor (ie, ezetimibe). Bempedoic acid plus ezetimibe resulted in a 36% reduction in LDL-C from baseline in a Phase 3 clinical trial.[78] Bempedoic acid is generally well tolerated and does not cause or contribute to muscle symptoms. However, bempedoic acid may cause hyperuricemia and tendon rupture. Increased blood concentrations of uric acid were seen in some patients treated with bempedoic acid and this may increase the risk of acute gout in those with a history of gouty arthritis. Mechanistically, bempedoic acid inhibits the renal tubular organic anion transporter 2 (OAT2), which plays a role in the renal uptake of uric acid from the blood. Though rare, bempedoic acid was associated with an increased risk of tendon rupture or injury (0.5%) in clinical trials. This uncommon but potentially debilitating adverse effect was not reported in patients who received a placebo. Risk factors for tendon rupture are age greater than 60 years, concurrent use of corticosteroids or fluoroquinolones, renal failure, and history of tendon disorders. Until the results of the long-term cardiovascular outcome trial are published, the role of bempedoic acid in the management of dyslipidemia should be limited to patients unable to achieve desired treatment goals on maximally tolerated statin plus ezetimibe who prefer a non-injectable therapeutic option.

Drug that Primarily Lower Triglycerides

Fibric Acid Derivatives (Fibrates)

Although fibrates, such as gemfibrozil, reduces cardiovascular events when used as monotherapy, there is less evidence to support their use in combination with statin therapy.[54,55] Fibrates are primarily used in patients with TG levels that exceed 500 mg/dL (5.65 mmol/L) to reduce the risk of acute pancreatitis. The two available fibrates, gemfibrozil and fenofibrate, are potent TG-lowering therapies (20%-50%), but may cause a modest reciprocal rise in LDL-C in patients with severely elevated TG levels.[55] Plasma HDL-C concentrations may rise 10% to 15% or more with fibrates. Gemfibrozil increases the activity of LPL and reduces to a lesser extent the synthesis or secretion of VLDL from the liver into the plasma. Fenofibrate increases LPL activity and reduces apoprotein C-III (an inhibitor of LPL) by activating peroxisome proliferator-activated receptor α (PPARα), which regulates the expression of genes involved in the regulation of lipids and other metabolic processes.

Fibrates are generally well tolerated, but gastrointestinal complaints and transient elevations in transaminase levels have been reported.[79] Both gemfibrozil and fenofibrate require dose adjustments for significant renal impairment and fenofibrate has been reported to worsen renal function, although this is usually transient and self-limiting.[17,80] Muscle-related adverse effects can occur with both gemfibrozil and fenofibrate alone but is more common when used in combination with statins to manage complex dyslipidemia or elevated TG levels. Gemfibrozil, and its glucuronide metabolite, has potent effects on CYP450 enzymes (ie, CYP3A4), intestinal, hepatic, and renal transporters making it highly prone to significantly increase serum statin concentrations and the risk of SAMS.[64] For this reason, current guidelines do not recommend gemfibrozil to be initiated in patients receiving statin therapy; fenofibrate is favored instead.[17] Fenofibrate and gemfibrozil and may enhance the formation of gallstones, but this occurs rarely.[81] Fibrates may potentiate the effects of warfarin and the international normalized ratio (INR) should be monitored closely with this combination.[82]

Omega-3 Polyunsaturated Fatty Acids (PUFA)

High doses of omega-3 PUFA (2-4 g/day of EPA/DHA) significantly reduce TG and VLDL cholesterol levels (20%-50%) with lesser effects on other lipoproteins.[54] The mechanisms by which omega-3 PUFA reduce TG levels include increasing hepatic oxidation of free fatty acids, increasing LDL hydrolysis by activating PPARα, and inhibiting apoprotein C-III. The omega-3 PUFA formulations approved by the FDA for treating TG levels of 500 mg/dL (5.65 mmol/L) or greater include an omega-3-acid ethyl ester of EPA/DHA (Lovaza®), omega-3-carboxylic acid of EPA/DHA (Epanova®), and ethyl ester of EPA only (Vascepa®). DHA and EPA have different effects on LDL-C as EPA prevents LDL oxidation and promotes LDL clearance, whereas DHA does not; however, the clinical significance of this remains unclear.[83] Prescription omega-3 PUFA products contain approximately 1 g of EPA/DHA per capsule, whereas the EPA/DHA content of OTC "fish oil" supplements is often less than 300 mg/capsule and are not regulated by the FDA. Unless patient affordability is an issue, prescription omega-3 PUFA are preferred to minimize pill burden and ensure product quality.

Randomized clinical trials of omega-3 PUFA have shown mixed results due to the lack of generalizability due to the population studied, the background lipid-lowering therapy used, and the dose taken.[83] Table 32-7 lists select TG lowering and cardiovascular trials of available omega-3 PUFA products. The REDUCE-IT study evaluated the effects of icosapent ethyl (4 g/day), a high-potency EPA derivative, used as add-on therapy to statins compared to mineral oil placebo.[84] At baseline, patients enrolled in the REDUCE-IT study had a median TG level of 216 mg/dL (2.44 mmol/L) and the majority had a history of ASCVD. Icosapent ethyl reduced the rate of ischemic events by 25% and significantly reduced the risk of cardiovascular death when compared to placebo. This benefit is not related to TG reduction, however, and may be due to increases in EPA levels. In contrast, the STRENGTH trial evaluated the omega-3-carboxylic acid of EPA/DHA in a randomized controlled trial using corn oil placebo in a population similar to that of REDUCE-IT; however, there was no observed benefit with the intervention.[85] The debate is ongoing as to why these trials produced completely different results, including differences in the omega-3 PUFA product used (EPA only vs EPA/DHA) and type of placebo used (mineral oil vs corn oil).

TABLE 32-7

Select Clinical Trials of Omega-3 PUFA Effects on TG Lowering and Cardiovascular Events

Product	**Omega-3 Acid Ethyl Esters (Lovaza)**	**Icosapent Ethyl (Vascepa)**	**Omega-3 Carboxylic Acids (Epanova)**
Indicated uses	To reduce TG in adults with severe hypertriglyceridemia (TG ≥500 mg/dL [5.65mmol/L])		
		Reduce major vascular events in adults with elevated TG (150-499 mg/dL [1.70-5.64 mmol/L]) and elevated cardiovascular risk while taking statin therapy	
Omega-3 fatty acid contents (per 1 g)	465 mg EPA 375 mg DHA	1 g EPA	550 mg EPA 200 mg DHA
TG-lowering efficacy in patients w/TG ≥500 mg/dL	**Harris et al.**[90] Patients with TG 500-2,000 mg/dL (5.65-22.6 mmol/L) Intervention: 4 g/d EPA+ DHA ethyl esters vs placebo TG-lowering from baseline: −45% vs +16%	**MARINE** Patients with TG 500-2,000 mg/dL (5.65-22.6 mmol/L) Intervention: 4g/d EPA vs placebo TG-lowering from baseline: −26.6% vs +9.7%	**EVOLVE** Patients with TG 500-2,000 mg/dL (5.65-22.6 mmol/L) Intervention: 4g/d EPA+DHA carboxylic acids vs 4 g/d olive oil TG-lowering from baseline: −30.9% vs -4.3%

Gastrointestinal complaints (ie, abdominal pain and “fishy burps”) are common with omega-3 PUFA products but may be minimized by refrigerating the capsules. However, they should not be kept frozen in the freezer. Caution is advised in patients with known sensitivities or allergies to fish or shellfish. Drug-drug interactions are minimal with omega-3 PUFA, although caution is advised when used concomitantly with antiplatelet agents or anticoagulants since omega-3 PUFA may prolong bleeding time. Both low- and high-dose omega-3 PUFA supplementation has been observed to increase the risk of incident atrial flutter or fibrillation.[86]

Niacin

Niacin (nicotinic acid) increases HDL-C (5%-30%), and lowers TG (20%-50%) and LDL-C (5%-20%). Despite these favorable changes in the lipid profile, niacin has not been shown to improve cardiovascular outcomes in patients on background statin therapy with relatively well-controlled lipids at baseline.[58,59] Niacin primarily lowers TG levels by inhibiting lipolysis with a decrease in free fatty acids in plasma and decreased hepatic esterification of TG. It also significantly raises HDL-C by reducing its catabolism and selectively decreasing hepatic removal of HDL apoA-I but not the removal of cholesterol esters, thereby increasing the capacity of retained apoA-I to augment reverse cholesterol transport in isolated hepatic cells. Niacin also reduces the hepatic synthesis of VLDL, which, in turn, leads to a reduction in the synthesis of LDL. However, the modest decrease in serum LDL-C levels is dose-dependent.

Niacin has many adverse drug reactions that frequently limit its use. Cutaneous flushing and itching are prostaglandin mediated and can be reduced by administering aspirin 325 mg given shortly before niacin ingestion.[91] Flushing seems to be related to rising plasma concentrations of niacin and the use of immediate-release formulations; taking the dose with meals and slowly titrating the dose upward may also minimize these effects. Extended- or sustained-release products may minimize these complaints in some patients. The only legend form of niacin, Niaspan® (Abbott), is an extended-release form of niacin with pharmacokinetics intermediate between immediate- and sustained-release products that are sold as food supplements rather than legend products. In controlled trials, Niaspan® is reported to have fewer dermatologic reactions and has a lower risk for hepatoxicity.[91] Potentially important laboratory abnormalities occurring with niacin therapy include elevated liver function tests, hyperuricemia, and hyperglycemia. With less than 3 g/day, the degree of liver function test elevation is generally not marked and often transient, and a temporary reduction in dosage frequently corrects the problem. Pre-existing gout and diabetes may be exacerbated by niacin; these patients should be monitored more closely and their medication titrated appropriately.[92,93] Niacin is contraindicated in patients with active liver disease and active peptic ulcer disease. Concomitant alcohol and hot beverages may magnify flushing and pruritus with niacin and they should be avoided at the time of ingestion. Nicotinamide should not be used in the treatment of hyperlipidemia, as it does not effectively lower cholesterol or TG levels.

Special Populations

Older Adults

Dyslipidemia is an independent risk factor for ASCVD in older adults (older than 65 years), as it is in younger patients.[94] The attributable risk, which is the difference in absolute rates of cardiovascular events between segments of the population with higher or lower serum cholesterol levels, increases with age. Drug therapy in principle differs little from younger patients, and older patients respond to lipid-lowering therapies as well as younger patients. Primary prevention in younger patients requires about 2 years before reduction in ASCVD risk is apparent, and this lag time should be taken into consideration, along with life expectancy, when determining if statin therapy is appropriate in older adults. The gain in life expectancy may be small depending on the age at the start of treatment and the magnitude of LDL-C reduction. The benefits of moderate-to-high intensity statin therapy in older adults for secondary prevention is quite clear, while the benefit of statins in older adults for primary prevention is more controversial.[94] This is especially true in individuals older than 75 years since this age group is poorly represented in RCTs.[17] One observational cohort study assessed cardiovascular events among a cohort of patients aged 75 years with no previous ASCVD who either continued or discontinued statin therapy prior to their 75th birthday.[95] Compared to patients who continued, patients who discontinued statin therapy had a 33% increased risk of being admitted for a cardiovascular event. A posthoc meta-analysis of the JUPITER and HOPE-3 primary prevention trials assessed major cardiovascular events by age (<65 years, 65-69 years, and 70 years or older).[96] Combined results of both trials reported that statin treatment was associated with a 26% lower risk of major cardiovascular events among patients aged 70 years or older, but was only significant within the JUPITER population. The ongoing Statin Therapy for Reducing Events in the Elderly (STAREE) trial (NCT02099123) is evaluating the efficacy of atorvastatin 40 mg/day for primary prevention in those 70 years or older without diabetes and will provide additional information as to the benefits of statin for primary ASCVD prevention in the elderly.

The risks of statin therapy in older adults must also be considered. Changes in body composition, renal function, and other physiologic changes of aging may make older patients more susceptible to the adverse effects of lipid-lowering drug therapy.[94] Older adults are more prone to developing SAMS and the effects of SAMS on the risk of falls and functional status remains unclear.[83] There is also concern regarding the potential negative effects of statins on cognitive function; however, data from meta-analyses have suggested statins are not associated with adverse cognitive effects.[97,98] Statin use has also been associated with increased risk of cataracts, which is highly prevalent among older adults, yet a meta-analysis found no clear evidence showing statins increase the risk of cataracts.[99] Older adults are also more likely to develop type 2 diabetes and the impact of statin therapy on new-onset diabetes in older adults is a concern warranting further study. Several factors including worsening physical or cognitive function, multi- or worsening comorbidities, advancing frailty, and/or reduced life expectancy may favor discontinuing statin therapy in adults 75 years and older taking statins for primary prevention.[17] Clinician-patient discussion regarding potential benefits and risks of discontinuing statin therapy is recommended to ensure individualized treatment decisions.

Children

While cardiovascular events rarely occur in those under 18 years of age, the process of atherosclerosis often begins during childhood.[100] Early identification and management of risk factors is critical for primordial prevention of ASCVD. Dyslipidemia in children can develop from secondary causes, similar to adults, or may present as primary dyslipidemia (ie, FH). Universal lipid screening is recommended between age 9 and 11 years as this is a stable time for lipid assessment before the onset of puberty, which decreases cholesterol levels 10% to 20%.[100] Lipid screening before age 9 is only recommended in children with a significant family history of premature ASCVD, known first-degree relatives with dyslipidemia, or other cardiovascular risk factors (ie, diabetes, obesity, or hypertension).[100]

Drug therapy in children is not recommended until the age of 10 years or older and the guidelines for initiation of therapy and acceptable levels of cholesterol and lipoproteins are quite different that adults.[100] Children younger than 10 years should only receive drug therapy if they have a genetic lipid disorder (ie, FH) or high-risk ASCVD condition (ie, diabetes); these children should be referred to a pediatric lipid specialist.[100] Lifestyle interventions are generally the mainstay of therapy, yet children with FH will often require drug therapy. Rosuvastatin may be used in children with HoFH at age 7. Pravastatin, Pitavastatin, and rosuvastatin may be used in children as young as 8 years, while all other statins are indicated for use in children 10 years of age and older.[100] Start with the lowest available statin dose and titrate every 3 months as necessary to achieve treatment goals. Appropriate contraception strategies are recommended in females taking statins who are sexually active. Ezetimibe and BAS also have data suggesting that they are safe and effective to use in children aged 10 years or older. Now, evolocumab is the only PCSK9 inhibitor with safety and efficacy data in children aged 13 years or older with HoFH.[101] The safety and efficacy of fibrates and omega-3 PUFA have not been established.

Women

The leading cause of death in women is ASCVD and as many women as men die of ASCVD annually. This is mostly due to a longer average life expectancy and a higher lifetime risk of ischemic stroke than men.[102] Age is an important factor when estimating cardiovascular risk in women as most ASCVD events occur in postmenopausal women. The decline in estrogen levels that occurs during menopause is associated with increased cardiovascular risk, yet hormone replacement therapy is not recommended as studies have shown it does not reduce cardiovascular risk.[103,104] Other age-related changes, including increases in blood pressure and LDL-C, play a significant role as well in both women and men. Women have been underrepresented in RCT of lipid-lowering therapies; however, a meta-analysis of 27 RCTs found that statin therapy is equally effective in men and women.[105] Nonstatin therapies also appear to be equally effective except for fenofibrate, which is associated with an increased ASCVD risk in women when combined with simvastatin.[106] This finding was not, however, observed in another RCT comparing fenofibrate to placebo.[107] The clinical significance of this subgroup finding remains unknown.

Pregnancy is associated with a progressive rise in cholesterol and TG levels, yet dietary therapy is the mainstay of treatment, with emphasis on maintaining a nutritionally balanced diet as per the needs of pregnancy.[108] If the patient is at high risk or has FH, a BAS may be considered during pregnancy since there is no systemic drug exposure.[108] In July 2021, the FDA recommended that statins no longer be considered contraindicated in pregnant patients, but may be used in select pregnant patients with a high risk of cardiovascular events. Most pregnant patients should still be advised to discontinue statin treatment; statin use while breast feedings is not recommended. Women of childbearing age who are on statin therapy and are sexually active should use a reliable form of contraception to prevent pregnancy. Women who plan to become pregnant should discontinue the statin 1 to 2 months before pregnancy is attempted. Ezetimibe and niacin are pregnancy category C drugs but no data are available in humans. Increased intake of omega-3 PUFA, particularly DHA, during pregnancy is important for fetal brain development; however, prescription omega-3 PUFA products are pregnancy category C.[109] There is no information on the safety of PCSK9 inhibitors in pregnant women.

Patients with Diabetes

Diabetes is a major risk factor for ASCVD and persons with type 1 or type 2 diabetes are at greater risk of morbidity and mortality following an ASCVD event.[17] The dyslipidemia commonly found in persons with diabetes is often characterized by hypertriglyceridemia, low HDL-C, and modestly elevated, but dense, LDL-C that are highly atherogenic.[110] Despite the modest elevation in LDL-C observed in these patients, statins are the first-line therapy given the significant body of evidence from RCT demonstrating that statins reduce ASCVD events and mortality in persons with diabetes.[17] However, the risk among those with diabetes who have no history of ASCVD is not homogenous, so the 10-year ASCVD-risk score may be used to determine the appropriate statin intensity (see Table 32-5 and Figure 32-6).[17] High-intensity statin therapy is preferred in those with diabetes and a history of ASCVD (secondary prevention) given these patients are at high risk of recurrent ASCVD events.

The role of nonstatin therapies in persons with diabetes is complex but has become clearer in recent years. In the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) the benefit of adding ezetimibe to simvastatin was significantly enhanced in those with diabetes compared to patients without diabetes.[111] The addition of evolocumab to background statin therapy in the Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Subjects With Elevated Risk (FOURIER) trial was equally effective in those with, and without, diabetes.[112] Given the mixed dyslipidemia associated with diabetes, there has been considerable interest in the potential of fibrates to reduce ASCVD risk. However, in the Action to Control Cardiovascular Risk in Diabetes (ACCORD), the combination of fenofibrate and a statin in patients with type 2 diabetes did not reduce the rate of fatal cardiovascular events, nonfatal myocardial infarction, or nonfatal stroke compared to simvastatin alone.[106] Subgroup analyses from two RCTs have suggested a potential benefit with fenofibrate in those with TG levels >204 mg/dL (2.31 mmol/L) and HDL-C <34 mg/dL (0.88 mmol/L), but this has not been evaluated in a prospective RCT.[106,107] Additionally, fenofibrate reduces the progression of diabetic retinopathy, as well as the need for laser treatment.[113] The BAS colesevelam is FDA-approved to improve both glycemic and lipid control, but it can exacerbate hypertriglyceridemia, which is commonly observed in those with diabetes.[55] Niacin modestly increases fasting plasma glucose (~4%-5%) and HbA1c levels (~0.25%).[92] As such, niacin should not be routinely used in persons with diabetes especially given the lack of evidence to support its use.

Patients with Kidney Disease

Dyslipidemia is highly prevalent among patients with kidney disease.[114] The dyslipidemia pattern in patients with kidney disease includes hypertriglyceridemia, slightly elevated total cholesterol, and LDL-C and low HDL-C levels.[114] These abnormalities are thought to be caused by a deficiency in apolipoprotein C-II, perhaps as a result of sustained use of heparin during hemodialysis and depletion of LPL, carbohydrate-induced obesity and hypertriglyceridemia, loss of carnitine during hemodialysis, use of acetate buffer (acetate is a precursor to fatty acid synthesis) during hemodialysis, and decreased LCAT activity during hemodialysis.[115] Dialysis does not correct the lipid abnormalities. Renal transplantation may correct lipid abnormalities in some patients; however, in others, the use of transplantation-related medications, such as corticosteroids and cyclosporine may aggravate lipid abnormalities.[115]

Statins effectively reduce LDL-C in patients with kidney disease, yet the cardiovascular event reduction is less robust in patients with kidney disease.[114] Notably, rosuvastatin failed to prevent cardiovascular events in a RCT of patients undergoing hemodialysis suggesting statins should not be initiated in this population.[116] Statins are generally continued, however, in patients who are on statins before progressing to end-stage renal disease and requiring dialysis.[114] Moderate-intensity statins are generally preferred in patients with kidney disease to minimize the risk of adverse effects (ie, SAMS).[114] Kidney transplant recipients are at considerably high risk of future cardiovascular events and should receive statin therapy; however, appropriate statin selection is important given the potential for drug-drug interactions with antirejection therapies (ie, cyclosporine).[114] Ezetimibe may also be used in combination with statin therapy based on RCT evidence showing that this combination reduces cardiovascular events compared to placebo in patients at various stages of advanced kidney disease.[117] Current guidelines do not advocate for routine use of other nonstatin therapies, given the paucity of efficacy data and safety concerns.[114]

Patients with Chronic Inflammatory Disorders and HIV

It is well established that chronic inflammation and immune activation occur with chronic inflammatory disorders (eg, rheumatoid arthritis, lupus) and human immunodeficiency virus (HIV) and this accelerates the development and progression of atherosclerosis. These nontraditional risk factors are not included in the ASCVD-risk estimator, but they should be considered when assessing individual ASCVD risk. After a 3- to 6-month trial of lifestyle interventions, these patients should have their 10-year ASCVD risk estimated. In those with a 10-year ASCVD risk of 5% or greater, it is reasonable to initiate moderate-intensity statin therapy.

In addition to considering statin therapy, there are additional considerations with the treatments used for chronic inflammatory disorders and HIV. Long-term use of antiretroviral therapy, for example, mediates atherosclerosis progression and development in patients with HIV. Many antiretrovirals (eg, protease inhibitors) can significantly increase TG levels. Anti-inflammatory therapies (eg, tociluzimab, methotrexate) used in the management of rheumatoid arthritis have produced mixed results in terms of their effects on lipid levels and ASCVD risk.

EVALUATION OF THERAPEUTIC OUTCOMES

Short-term evaluation of therapy for dyslipidemia is based on a complete lipid panel obtained 4 to 12 weeks after initiation or following a dose adjustment of lipid-lowering therapy to evaluate therapeutic response.[17] This is especially important with statin therapy given there are numerous pharmacokinetic and pharmacodynamic differences among statins that give rise to variable response to therapy.[118] Long-term evaluation is based on a repeat lipid panel obtained every 3 to 12 months to ensure adherence to lipid-lowering therapy and maintenance of desired levels of LDL-C.[17] It should be noted that although total cholesterol (TC) HDL-C, and TG levels are directly measured, LDL-C is typically estimated using the Friedewald equation, LDL-C = TC – HDL-C – (TG/5) (or LDL-C = TC – HDL-C – [TG/2.2] when lipid levels are all expressed in mmol/L), which does not provide an accurate estimate of VLDL-C.[119] As such, the Friedewald equation can underestimate LDL-C in patients with high TG levels as well as those with very low LDL-C levels. Given VLDL-C concentrations are typically small in comparison to LDL-C, the inaccuracy of VLDL-C has previously been accepted. However, given the increased prevalence of obesity, metabolic syndrome, and diabetes, more patients have elevated levels of VLDL-C. Useful alternatives in these patients include non-HDL-C (TC minus HDL-C) and direct LDL-C measurements, which are more accurate than estimated LDL-C using the Friedewald equation.[119] A nonfasting lipid panel is generally acceptable, except in patients with hypertriglyceridemia, where a fasting lipid panel is preferred to minimize interference from chylomicrons.[120] Routine safety monitoring of hepatic function and CK levels is not recommended in statin-treated patients, but these may be obtained if the patient has signs or symptoms suggestive of liver or muscle injury.[17] Patients taking niacin, on the other hand, should have hepatic function tests performed at baseline, after each dosage increase, and every 6 months thereafter while taking a stable dose.[17] Periodic monitoring of A1c is warranted in persons with diabetes receiving niacin and patients treated with statins who are at high risk for developing diabetes.[17]

In patients treated with lipid-lowering therapy for secondary prevention, symptoms such as angina or intermittent claudication may improve over months to years. If patients have xanthomas or other external manifestations of dyslipidemia, these lesions should regress with therapy.[50] Modifiable risk factors such as hypertension, smoking, exercise and weight control, and glycemic control in persons with diabetes should also be monitored and evaluated.[17,27] Dietary therapy is an important part of treating dyslipidemia and a dietitian should be consulted to perform an initial evaluation with periodic follow-up thereafter if the goals of therapy are not achieved.[24] Use of food diaries and recall surveys enable the collection of information about diet in a systematic manner and may improve patient adherence to dietary recommendations.

ABBREVIATIONS

ACL	adenosine triphosphate-citrate lyase
Apo	apolipoprotein
ASCVD	atherosclerotic cardiovascular disease

ALT	alanine transaminase
ANGPTL3	angiopoietin-like 3
AST	aspartate transaminase
ATP	adenosine triphosphate
BASs	bile acid sequestrants
BMI	body mass index
BUN	blood urea nitrogen
CE	cholesterol ester
CETP	cholesterol ester transfer protein
CHD	coronary heart disease
CKD	chronic kidney disease
CVD	cardiovascular disease
DHA	docosahexaenoic acid
EPA	eicosapentaenoic acid
HbA1c	glycosylated hemoglobin A1c
HDL-C	high-density lipoprotein-cholesterol
HIV	human immunodeficiency virus
HMG-CoA	β-hydroxy β-methylglutaryl coenzyme A
HTN	hypertension
IDL-C	intermediate-density lipoprotein-cholesterol
LCAT	lecithin-cholesterol acyltransferase
LDL-C	low-density lipoprotein-cholesterol
LPL	lipoprotein lipase
LRP	LDL-receptor-related protein
NPC1L1	Niemann-Pick C1-like1
OTC	over-the-counter

PCOS	polycystic ovarian syndrome
PSCK9	proprotein convertase subtilisin/kexin type 9
PUFA	polyunsaturated fatty acid
RCT	randomized controlled trial
SAMS	statin-associated muscle symptoms
T2DM	type 2 diabetes mellitus
TC	total cholesterol
TG	triglyceride
TSH	thyroid-stimulating hormone
UA	urinalysis
VLDL-C	very-low-density lipoprotein-cholesterol

SELF ASSESSMENT QUESTIONS

1. Which of the following nonpharmacologic interventions would be most effective to lower LDL-C?

   A. Smoking cessation

   B. Increase daily intake of soluble fiber

   C. Complete 150 minutes per week of physical activity

   D. Reduce intake of sugar-sweetened beverages

2. Which of the following is the most appropriate therapy for a 64-year-old patient without a history of diabetes or ASCVD and a 10-year ASCVD risk score of 15.6%?

   A. Pravastatin 20 mg daily

   B. Rosuvastatin 10 mg daily

   C. Atorvastatin 40 mg daily

   D. Pitavastatin 1 mg daily

3. Which of the following is included in the ASCVD risk estimator?

   A. Family history

   B. Duration of diabetes mellitus

   C. Smoking status

   D. History of ASCVD

4. Which of the following factors is associated with a higher risk of developing statin-associated muscle symptoms (SAMS)?

   A. High body mass index

   B. Physical inactivity

   C. Male gender

   D. Kidney disease

5. Which of the following is the most appropriate initial approach to managing a patient experiencing statin-associated muscle symptoms (SAMS)?

   A. Switch to a non-statin lipid lowering medication

   B. Stop the statin for at least 2 weeks

   C. Add coenzyme-Q10

   D. Measure creatine kinase (CK) levels

6. Which of the following is the primary target for lipid-lowering therapy?

   A. Triglycerides

   B. Lipoprotein (a)

   C. High-Density lipoprotein cholesterol

   D. Low-Density lipoprotein cholesterol

7. Which of the following is the *LEAST* common familial dyslipidemia?

   A. Hypertriglyceridemia

   B. Homozygous familial hypercholesterolemia

   C. Heterozygous familial hypocholesteremia

   D. Combined hyperlipidemia

8. What is the rate-limiting step in the biosynthetic pathway for cholesterol?

   A. HMG-CoA reductase

   B. ABCA-1 inhibition

   C. Lipoprotein lipase

   D. Reverse cholesterol transport

9. Which of the following would most likely lower triglyceride levels?

   A. Increase soluble fiber intake

   B. Phytosterol 2 grams/day supplementation

   C. Alcohol abstinence

   D. Smoking cessation

10. Which medication reduces triglyceride levels by activating peroxisome proliferator-activated receptor α?
    - A. Ezetimibe
    - B. Niacin
    - C. Omega-3 fatty acids
    - D. Fenofibrate
11. What is the LDL-C threshold to consider adding ezetimibe and/or PCSK9 mAb to maximally tolerated statin therapy in a patient who is at very high risk ASCVD?
    - A. ≥50 mg/dL
    - B. ≥70 mg/dL
    - C. ≥100 mg/dL
    - D. ≥130 mg/dL
12. Which of the following patients is at the highest risk for ASCVD?
    - A. 35-year-old with high blood pressure
    - B. 47-year-old with type 2 diabetes mellitus
    - C. 59-year-old with heart failure
    - D. 68-year-old with a history of MI and hypertension
13. Which non-statin has the greatest LDL-C lowering effect?
    - A. Ezetimibe
    - B. Bempedoic acid
    - C. PCSK9 mAbs
    - D. Bile acid sequestrants
14. What is the primary effect of omega-3 fatty acids on the lipid profile?
    - A. Lower LDL-C
    - B. Increase HDL-C
    - C. Lower triglycerides
    - D. Lower Lp(a)
15. Which omega-3 fatty acid product has been shown to reduce the risk of ASCVD events in patients with a history of ASCVD or high-risk patients with diabetes?
    - A. Omega-3 carboxylic acid (Epanova®)
    - B. Icosapent ethyl (Vascepa®)

C. Omega-3 acid ethyl esters (Lovaza®)

D. Over-the-counter (OTC) fish oil

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Increasing soluble fiber has been associated with lower LDL-C values. See Table 32-4 for more information on nonpharmacologic therapies and their effects on lipid parameters and ASCVD risk.

2. **B.** Moderate-intensity statin is recommended for primary prevention in patients with a 10-year ASCVD risk score. Rosuvastatin 10 mg daily is the only moderate-intensity statin listed. See Fig. 32-6 for assessment and treatment decision pathways for primary ASCVD prevention.

3. **C.** Age, gender, race, blood pressure, diabetes status, and smoking status are among the main patient-factors included in the ASCVD Risk Estimator. See ASCVD Risk Estimator is discussion in paragraph beginning with learning objective #5.

4. **D.** Kidney disease is a known risk factor for developing SAMS. See text discussing SAMS in the "HMG-CoA Reductase Inhibitors (Statins)" section and the section on treating dyslipidemia in patients with kidney disease.

5. **B.** Stopping the statin for at least 2 weeks is the initial step as this allows time for the symptoms to resolve, which increases the probability of SAMS. If symptoms do not resolve, then additional workup for other potential causes may be warranted. See text discussing SAMS in the "HMG-CoA Reductase Inhibitors (Statins)."

6. **D.** The primary target for lipid-lowering therapy is LDL-C due to its relationship to atherosclerotic cardiovascular disease (ASCVD). Even in cases of sub-types of dyslipidemia (eg, low HDL-C), LDL-C remains the primary target of therapy. See the section "Introduction" for more information on this.

7. **B.** Homozygous familial hypercholesterolemia is extremely rare with an estimated prevalence of one case per one million people, while heterozygous familial hypercholesterolemia is one of the most common genetic disorders affecting one in every 250 people. See the section "Primary or Familial Dyslipidemias" for more information on familial dyslipidemias and their specific descriptions.

8. **A.** HMG-CoA reductase is responsible for the development of cholesterol. HMG-CoA reductase is also the target for statin medications that are highly effective at reducing blood cholesterol, furthering the evidence for the rate-limiting nature of the enzyme. See the section "Lipoproteins and Cholesterol Synthesis" and Fig. 32-3 for more information on the biosynthetic pathway for cholesterol.

9. **A.** Alcohol is both a secondary cause of hypertriglyceridemia and a contributing factor to pancreatitis, which is a life-threatening risk of uncontrolled hypertriglyceridemia. See the section "Nonpharmacologic Therapy" and Table 32-4 for more information nonpharmacologic therapy to improve lipids.

10. **D.** Fenofibrate is a PPAR α agonist that regulates the expression of genes involved in several metabolic processes. See the section "Drugs that Primarily Lower Triglycerides" for more information on these therapeutic options.

11. **B.** An LDL-C threshold of ≥70 mg/dL warrants consideration of either adding ezetimibe and/or a PCSK9 mAb to maximally tolerated statin therapy. This is based on randomized controlled trial evidence and ensures that additional LDL-C lowering therapies are used in patients at very high risk ASCVD who are most likely to benefit. See Fig. 32-7 and the section "General Approach" for more information.

12. **D.** Very-high risk ASCVD is classified as either having ≥2 major ASCVD events OR 1 major ASCVD event AND ≥2 high-risk conditions. The scenario in option D meets this definition as it includes 1 major ASCVD event (history of MI) and two high-risk conditions (≥65 years old and hypertension). See Fig. 32-7 for more information.

13. **C.** The PCSK9 mAbs, alirocumab and evolocumab, reduce LDL-C levels by approximately 60% and are the most potent non-statin LDL-C lowering agents. Ezetimibe, bempedoic acid, and bile acid sequestrants modestly reduce LDL-C levels by approximately 15% to 25%. See section, "Medications that Primarily Lower Atherogenic Cholesterol" for more information.

14. **C.** Omega-3 fatty acids primarily reduce triglycerides through multiple mechanisms. When used as monotherapy, omega-3 fatty acids can increase LDL-C levels or have a neutral effect. The increase in HDL-C observed with omega-3 fatty acids is quite modest and omega-3 fatty acids do not appear to lower Lp(a). See section, "Omega-3 Polyunsaturated Fatty Acids (PUFA)" for more information.

15. **B.** In the REDUCE-IT trial, the addition of 4g/d of icosapent ethyl to background statin therapy reduced ASCVD events. No other omega-3 fatty acid product has been shown to reduce the risk of ASCVD events. See section, “Omega-3 Polyunsaturated Fatty Acids (PUFA)” and Table 32-7 for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 33: Stable Ischemic Heart Disease

Paul P. Dobesh; Robert J. DiDomenico; Kelly C. Rogers

KEY CONCEPTS

KEY CONCEPTS

① Stable ischemic heart disease (SIHD) is caused by an obstructive atherosclerotic plaque in one or more epicardial coronary arteries. Increases in myocardial oxygen demand in the setting of a fixed decrease in myocardial oxygen supply result in myocardial ischemia. Some patients with SIHD may have a component of vasospasm that requires a slightly different pharmacologic approach.

② Chest pain (angina) from exertion is the cardinal symptom of myocardial ischemia in patients with SIHD.

③ Assessment of successful treatment of angina includes reducing the number of episodes, enabling patients to participate in activities that provide a high-level quality of life, and decreasing mortality by using guideline-directed medical therapy (GDMT).

④ Management of modifiable atherosclerotic risk factors is key to improving the quantity of life in patients with SIHD.

⑤ Aspirin, angiotensin-converting enzyme inhibitors, and statins play an important role in preventing adverse cardiovascular events in patients with SIHD.

⑥ β-blockers are typically regarded as first-line therapy in the management and control of episodes of angina in patients with SIHD.

⑦ Calcium channel blockers, long-acting nitrates, and ranolazine are often used as additional therapies for angina. Calcium channel blockers and nitrates are first-line therapies in vasospastic disease.

⑧ All patients with SHID should receive sublingual nitroglycerin for acute treatment and should receive education regarding its proper use.

⑨ Revascularization procedures may provide a survival advantage over GDMT in SIHD patients with more extensive atherosclerotic disease but have not demonstrated a clear advantage over GDMT in those with less extensive disease. Antithrombotic therapy is necessary after revascularization for a variable duration of time.

BEYOND THE BOOK

BEYOND THE BOX

To better understand the normal physiology of the heart and the pathophysiology of coronary artery disease (CAD) please watch the following videos. These videos are useful to enhance learner's understanding regarding the COLLECT and ASSESS steps in the Patient Care Process.

1. Pathophysiology of CAD—What is Coronary Artery Disease? Khan Academy: https://tinyurl.com/y3cjyb8v (Duration: 13:38 minutes)
2. Myocardial oxygen supply—University of British Columbia, UBC Anesthesiology: https://tinyurl.com/yxjouoh3 (Duration: 4:59 minutes)
3. Myocardial oxygen demand—University of British Columbia, UBC Anesthesiology: https://tinyurl.com/y5488brm (Duration: 4:37 minutes)

INTRODUCTION

Coronary artery disease (CAD) is the leading cause of ischemic heart disease and is typically the result of atherosclerotic plaques in the epicardial vessels. The process of atherosclerosis begins early in life, with fatty steaks developing in many people in their teenage years or early twenties. These plaques grow over decades and start to become pathologic in a person's fifth decade of life and beyond. In addition to CAD, atherosclerosis also manifests in other vascular beds leading to cerebrovascular disease (Stroke, Chapter 39) and peripheral arterial disease (Chapter e35). Ischemic heart disease may present as an acute coronary syndrome (ACS) (Chapter 34), which includes unstable angina, non-ST-segment myocardial infarction (MI), or ST-segment elevation MI. While the pathophysiology is similar, stable ischemic heart disease (SIHD) is not an acute event but rather manifests as either chronic stable exertional angina or ischemia without clinical symptoms (silent ischemia). Less common causes of SIHD include microvascular angina, which is due to atherosclerosis in endocardial instead of epicardial vessels. Microvascular angina is more common in women and those with metabolic syndrome. Coronary vasospasm represents a form of angina that results from an increase in coronary vascular tone that can occur in either normal or diseased vessels. Prinzmetal's angina is a form of vasospastic angina that does not involve atherosclerotic plaque. Inappropriate, insufficient, or untreated SIHD can lead not only to MI and cardiac death, but also the development of heart failure (HF), arrhythmias, and valvular disease. The American College of Cardiology (ACC) and American Heart Association (AHA) have published guidelines for the diagnosis and management of SIHD.[1]

EPIDEMIOLOGY

According to AHA statistics, in 2018, an estimated 126.9 million (49%) adult Americans had at least one form of cardiovascular disease (CVD), which includes CAD, HF, stroke, and hypertension (HTN).[2] Among patients with CVD, approximately 20.1 million adult Americans had CAD, corresponding to an estimated prevalence of 7.2%. The prevalence of CAD increases with age and is higher in men. Among patients with CAD, the total number of patients with SIHD is difficult to determine. Statistics from the AHA estimate that approximately 11 million Americans have angina pectoris while the prevalence of MI among adult Americans is approximately 8.8 million, together approximating the prevalence of CAD.[2] Stable angina is the initial manifestation of ischemic heart disease in approximately one-half of all patients who eventually have an MI.

The mortality and costs associated with CAD are enormous. In 2018, CVD was the number one cause of death in the United States with CAD being the most common cause of CVD death, accounting for almost 400,000 deaths—42% of all CVD-related mortality.[2] Adjusting for age, death rates per 100,000 are highest among black patients compared to those of white and Hispanic ancestry and among men compared to women within each racial demographic. The estimated direct and indirect cost of CAD was $220 billion in 2016-2017, with direct healthcare spending of $89 billion.[2]

The prognosis of patients with SIHD is related to the extent of atherosclerotic disease, the presence of left ventricular (LV) dysfunction, and the presence of other comorbidities. The severity of angina symptoms may also be useful in determining the prognosis.[3] In a study of veterans with CAD, the risk of death increased with the degree of self-reported physical limitation due to angina.[4] It is thought that the degree of physical limitation reflects the extent of underlying atherosclerotic disease. In addition to mortality, SIHD leads to significant morbidity. Most patients will eventually need to be hospitalized for ACS. Patients often have a reduced quality of life due to their inability to perform activities of daily living without chest pain.[5,6] Time lost from work and lost productivity have a large indirect cost to patients and society. Approximately 15% to 20% of patients rate their health as fair or poor despite revascularization, and 30% of patients are never able to return to work.[7]

ETIOLOGY AND PATHOPHYSIOLOGY

① Angina pectoris is most often the result of an imbalance between myocardial oxygen supply and myocardial oxygen demand (MVO_2). The process of maintaining adequate coronary blood flow to meet the metabolic demands of the myocytes is complex. Multiple factors influence the supply/demand equation.

The pathophysiology of SIHD is driven by an increase in MVO_2 in the setting of a fixed decrease in myocardial oxygen supply.[8] The etiology of the fixed decrease in supply is long-standing, well-developed atherosclerotic plaque. These plaques grow over several decades. The extent and rate of growth are related to risk factors such as smoking, dyslipidemia, HTN, diabetes mellitus (DM), and genetics. The process and development of atherosclerosis are detailed in Chapter 32 (Dyslipidemia). Unlike ACS, the episodes of angina in patients with SIHD are not caused by ruptured atherosclerotic plaque, which leads to thrombus formation and a rapid reduction in coronary blood flow.[9,10] Rather, the atherosclerotic plaques are stable, have a reduced lipid core, and a firm calcified covering. Since the vessel lumen size does not acutely change, the atherosclerotic plaque produces a relatively fixed decrease in myocardial oxygen supply.

Determinants of Myocardial Oxygen Demand

The major determinants of MVO_2 include heart rate (HR), myocardial contractility, and intramyocardial wall tension. A twofold increase in any of these determinants requires an approximate 50% increase of coronary flow to maintain the myocardial oxygen supply. Intramyocardial wall tension is the leading contributor to increased MVO_2 and is directly related to the radius or size of the ventricular cavity and blood pressure (BP), and indirectly related to the ventricular muscle mass. The larger the size of the ventricular cavity, the more energy or myocardial work is needed for myocardial contraction (systole). During early systole, myocardial work peaks when the pressure in the LV overcomes the pressure outside the aortic valve. The aortic valve is then pushed open and blood is ejected into the systemic circulation. The higher the blood pressure outside the aortic valve, the more MVO_2 needed. Increased ventricular muscle mass should make myocardial work easier and reduce MVO_2. For example, some athletes have increased ventricular muscle mass and their heart works more efficiently. Unfortunately, left ventricular hypertrophy results in dysfunctional myocytes that do not improve MVO_2. Left ventricular hypertrophy can worsen the supply/demand balance because the blood vessel development (supply) is less than the native myocardium.

The rate-pressure product, or double product, is a common non-invasive measure of MVO_2. To determine the rate-pressure product, multiply the HR and systolic BP. However, changes in contractility or volume loading of the LV are not accounted for in this calculation. An increase in MVO_2 requirements commonly stems from the release of norepinephrine by adrenergic nerve endings in the myocardium and vascular bed as part of the physiologic response to exertion, emotion, or mental stress. The rate of increase of MVO_2, which correlates to the speed at which a physical task is carried out, can be as important as the total amount of MVO_2. A rapid increase in physical exertion is particularly likely to precipitate angina. Tasks involving motion of the hands over the head can also provoke chest pain. Mental and emotional stress may precipitate angina, presumably by increasing adrenergic tone and reducing vagal activity. Sexual activity may precipitate angina due to the combination of physical exertion and emotional stimulation. Similarly, anger can produce constriction of coronary arteries. Other precipitates of angina include physical exertion after a heavy meal and excessive metabolic demands imposed by chills, fever, exposure to cold, thyrotoxicosis, hypoglycemia, and other causes of tachycardia.

Determinants of Myocardial Oxygen Supply

Coronary Blood Flow

Meeting the metabolic demands of the myocardium is centered on the ability to maintain adequate coronary blood flow and coronary arterial pressure. The coronary vasculature is made up of larger epicardial vessels, also referred to as R_1 or conductance vessels, and smaller endocardial vessels called R_2 or resistance vessels (Fig. 33-1).[11] Resistance to coronary blood flow is the sum of the resistance in the R_1 and R_2 vessels. The larger epicardial vessels typically offer little resistance to blood flow and can accommodate large increases in coronary blood flow without producing a significant change in pressure. These vessels primarily serve a conduit function. In healthy coronary arteries, resistance to flow is controlled by smaller endocardial (R_2) vessels. These vessels will contract and dilate to maintain blood flow based on the metabolic demands of the myocardium. When a person is at rest or not engaged in physical activity, MVO_2 is low and endocardial vessels constrict. The need for blood flow is low. When there is physical exertion or emotional stress, MVO_2 increases and the endocardial vessels dilate to increase myocardial oxygen supply in proportion to the increase in MVO_2 (Fig. 33-1). The process of constricting and dilating the resistance vessels based on MVO_2 is called autoregulation.[8,11] In response to increased MVO_2, several vasodilatory substances (eg, nitric oxide, prostacyclin, and bradykinin) are secreted and this can increase coronary blood flow four- to fivefold over normal resting conditions.[8] The increase in coronary flow above resting conditions is the coronary flow reserve.

FIGURE 33-1

The coronary circulation with large epicardial conductance vessels (R_1) and intramyocardial resistance arterioles (R_2). Resistance to flow equals $R_1 + R_2$. R_2 resistance is normally much greater than R_1; hence, flow is equal to the driving pressure across the coronary bed divided by the resistance in R_2. Dilation in R_2 normally occurs in response to exercise or increased myocardial oxygen demand. When an atherosclerotic lesion narrows the conductance vessel, the arterioles dilate under resting conditions to prevent ischemia. However, during the period of exertion, the vasodilator reserve is limited. (*Reproduced from Epstein SE, O'Cannon R, Talbot TL. Hemodynamic principles in the control of coronary blood flow. Am J Cardiol. 1985;56:4E-10E.*)

Coronary atherosclerotic plaques typically develop in the larger epicardial vessels. As plaques grow and cause luminal narrowing, resistance to blood flow in epicardial vessels transforms from minimal to considerable. This continues to a point where the resistance from the epicardial vessels becomes dominant. Through autoregulation, the increase in resistance from the R_1 or conductance vessels is offset by vasodilation in the R_2 or resistance vessels to maintain flow.[11]

The luminal diameter occupied by the atherosclerotic plaque determines the drop in pressure and blood flow distal to the stenosis. The most important determinant of resistance for any given level of flow is the minimum stenosis cross-sectional area.[8] Because resistance is inversely proportional to the square of the cross-sectional area, small dynamic changes in the luminal area caused by atherosclerotic plaque size, thrombus creation, or vasospasm can lead to large changes in the stenosis pressure-flow relationship and reduce maximal perfusion during vasodilation.[8]

Coronary plaques that occupy less than 50% to 70% of the vessel luminal diameter are often referred to as "non-obstructive". They rarely produce ischemia or angina.[11] These smaller plaques do not produce symptoms, and therefore, the patient and clinician typically have no idea they exist. Small plaques have a rich lipid core and thin fibrous cap, they are more prone to rupture and provoke acute thrombus formation, making them potentially lethal (see Chapter 34 "Acute Coronary Syndrome").[9,10]

Once the epicardial vessel is narrowed by 70% or more of the luminal diameter, the endocardial vessels must fully dilate in order to maintain normal coronary flow. These larger plaques are considered "obstructive."[8,11] At this point, much of the coronary flow reserve has been used to preserve resting coronary blood flow and minimal physical exertion exhausts any remaining capacity. Further increases in exercise intensity are no longer accompanied by decreases in endocardial (R_2) resistance. Blood flow cannot increase to accommodate the demand and autoregulation has reached its ceiling. The resulting flow deficit causes myocardial ischemia and, frequently, angina. The amount of exertion a patient can endure is largely based on the extent of vessel stenosis and the remaining coronary flow reserve. The endocardial flow reserve is exhausted when the epicardial stenosis severity exceeds 90%. Narrowing of the luminal diameter by 90% or more is called a critical stenosis.

Heart Rate and Systole

Increasing HR not only increases MVO_2 but also reduces myocardial oxygen supply. While most tissues and organs are perfused during systole, the heart is the only organ that is perfused during diastole, the phase of myocardial relaxation. There are two physiologic explanations.[8] First, the pressure created in the ventricles during systole creates an increase in pressure in the coronary circulation well above the pressure for coronary perfusion (50-60 mm Hg). Only during diastole do the pressures drop sufficiently to allow coronary flow. Second, the physical compression force of the myocardium that occurs during systole squeezes the coronary vessels closed, preventing blood flow. During a typical cardiac cycle with a normal resting HR, the myocardium spends twice as much time in diastole compared to systole. When the HR increases, time spent in diastole is reduced while time in systole remains relatively unchanged. During times of exertion and increased HR, the ratio of time spent in diastole to systole is reduced from 2:1 to as little as 1:1. This reduces the time for myocardial perfusion, and thus, myocardial oxygen supply is significantly diminished.[8]

Oxygen Extraction and Oxygen Carrying Capacity

Two additional determinants of myocardial oxygen supply are myocardial oxygen extraction and oxygen-carrying capacity. The oxygen-carrying capacity of the coronary arteries is relatively fixed under normal circumstances and not capable of changing in response to increased MVO_2. Therefore, during exertion, the ability to increase oxygen delivery to myocytes is limited mainly through increasing oxygen extraction from the arterial blood. However, this compensatory mechanism provides little additional oxygen as myocardial arterial oxygen extraction is already approximately 75% under normal circumstances.[12]

Arterial oxygen content is related to hemoglobin concentration and oxygen saturation. Consequently, patients with anemia (low hemoglobin) or hypoxia (low oxygen saturation) have lower than normal oxygen-carrying capacity. Anemia is thought to impact total oxygen-carrying capacity to a greater degree than hypoxia until the oxygen saturation falls below 50% (0.50). This explains why patients with SIHD often require transfusions when hemoglobin concentrations fall below 9 to 10 g/dL (90-100 g/L; 5.59-6.21 mmol/L), whereas patients without SIHD can tolerate hemoglobin concentrations as low as 6 g/dL (60 g/L; 3.72 mmol/L). Most patients have arterial oxygen saturation between 95% and 100% (0.95 and 1.0) so oxygen therapy would not improve oxygen delivery. Therefore, there is little opportunity to improve myocardial oxygen supply by improving myocardial oxygen extraction or oxygen-carrying capacity, leaving increased myocardial blood flow as the principal mechanism for increasing myocardial oxygen supply.

Coronary Collateral Circulation

In the setting of SIHD, pre-existing collateral vessels develop in a process termed arteriogenesis. When coronary stenosis exceeds 70%, endocardial vessel pressure falls due to maximized autoregulation. This extent of stenosis also contributes to the severity and duration of the episodes of exertion-induced ischemia. The ischemic episodes stimulate nitric oxide synthase and lead to the production of vascular endothelial growth factor and basic fibroblast growth factor. The combination of altered coronary pressure, growth factors, and endogenous vasodilators (eg, nitrous oxide and prostacyclin) change native collateral vessels in existing epicardial anastomoses into mature vessels.[13] While most functional collateral flow develops from the process of arteriogenesis, collateral perfusion can also occur from the development of new collateral vessels in a process called angiogenesis. The process of angiogenesis is also driven by physical forces and growth factors but produces smaller, capillary-like vessels. These vessels can provide collateral flow in the border between ischemic and nonischemic regions of the myocardium.[13] Capillary angiogenesis may also occur within the ischemic region and can reduce the intercapillary distance for oxygen delivery.

Other Factors

While atherosclerotic coronary stenosis is the leading etiology in the development of SIHD and angina, there are additional pathophysiologic mechanisms that also contribute to disease onset and progression. These mechanisms include endothelial dysfunction, microvascular dysfunction, vasospasm, platelet activation, and coagulation, as well as inflammation.[13] A reduction in nitric oxide-mediated vasodilation leads to endothelial dysfunction. This can be due to impaired nitric oxide synthesis or availability. Reduced vasodilator response may lead to ischemia at lower levels of exertion. There can also be impairments that reduce microvascular response to endogenous vasodilators or exaggerate the response to vasoconstrictors.[13]

Patients with an ACS event have ruptured atherosclerotic plaque with platelet accumulation and coagulation response producing an acute reduction in myocardial oxygen supply.[9,10] While this is not the pathophysiology of ischemia in patients with SIHD, there can be smaller plaques (30%-50% stenosis) that rupture and produce a limited platelet and coagulation response that does not produce an acute compromise in myocardial oxygen supply. Instead, the thrombotic process is arrested and the thrombus undergoes re-endothelialization.[9] This greatly accelerates plaque accumulation. Finally, inflammation plays a role in the pathophysiology of SIHD. Macrophages and T lymphocytes produce and secrete cytokines, chemokines, and growth factors that activate endothelial cells, increase vasoreactivity, and proliferation of vascular smooth muscle cells.[13,14] C-reactive protein, a marker of inflammation, has been shown to be elevated in patients with SIHD and correlates to adverse CV events. Statin therapy in patients with elevated C-reactive protein and normal cholesterol levels reduces the risk of CV events.[15] While an obstructive atherosclerotic plaque contributes to ischemia and angina in patients with SIHD, the pathophysiology involves multiple mechanisms that can be used as therapeutic targets.

Coronary Vasospasm and Prinzmetal’s Angina

Most patients with SIHD have an obstructive coronary stenosis and exertion-induced ischemia. Since the size of the obstructive lesion does not change acutely, the amount of exertion needed to induce ischemia and angina is often predictable in an individual patient. For example, the patient knows that working in the garden for 20 minutes or walking five blocks at a certain pace will produce chest pain. Patients with this pattern of angina have a fixed angina threshold. Some patients have variable-threshold angina. In these patients, the amount of exertion needed to provoke chest pain differs from day-to-day. An example would be the patient who could walk six blocks before experiencing angina yesterday, but today they can only walk one block before becoming symptomatic. These patients have an obstructing atherosclerotic plaque leading to a fixed decrease in myocardial oxygen supply, but also have transient vasospasm superimposed at the site of the obstructing plaque.[11,13] The vasospasm at or distal to the location of atherosclerotic plaque is typically induced by endothelial damage. Damaged endothelial cells produce less than normal amounts of vasodilator substances such as endothelium-derived relaxing factor (EDRF) and often have an exaggerated response to vasoconstrictors during exercise.[13] Symptoms will differ based on the extent of the underlying fixed obstruction and the degree of dynamic change in coronary arterial tone. The changing pattern of ischemia in these patients reflects varying amounts of vasospasm. Angina episodes are typically more common in the morning hours due to the circadian release of vasoconstrictors. Exposure to cold temperature, emotion, and mental stress may also lower the angina threshold in patients with variable threshold angina.

Some patients have variant angina, also known as Prinzmetal’s angina. Patients with variant angina usually do not have flow-obstructing atherosclerotic plaques in their coronary arteries, but instead, have vasospasm in epicardial vessels.[8,13] The vasospasm is due to the reduced production of vasodilators and an exaggerated response to endogenous vasoconstrictors. Patients with Prinzmetal’s angina also have a different clinical presentation when compared to patients with SIHD due to an obstructive coronary plaque. Patients with Prinzmetal’s angina are typically younger, may experience chest pain at rest, often in the early morning, and have transient ST-segment elevation on the electrocardiogram (ECG).

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Stable Ischemic Heart Disease (SIHD)

General

- The patient is not typically in acute distress; however, careful assessment to identify features consistent with ACS is important.

Symptoms

- The classic symptom of ACS is abrupt-onset substernal chest pain or discomfort often described as a squeezing, heaviness, or tightness (Table 33-1). Symptoms may radiate to the arms, shoulders, back, abdomen, or jaw. Nausea, vomiting, diaphoresis, or shortness of breath may also be present.
- The PQRST pneumonic (Table 33-2) is useful for structuring the patient interview to assess the history of chest pain.
- Evaluation of symptoms should include an evaluation of the limitations in daily activities due to angina (eg, CCS classification, see Table 33-3).

Signs

- BP may be elevated in patients with SIHD
- No physical findings are specific for SIHD. Nonspecific findings include S4 or paradoxical splitting of S2 on auscultation.
- Patients with SIHD may present with signs of HF, including jugular venous distention, pulmonary edema, and an S3 on auscultation.

Laboratory Tests

- Cardiac troponin (cTn, either cTnI or cTnT) are not typically elevated in patients with SIHD.
- Fasting lipid panel should be evaluated to assess for the presence of dyslipidemia.
- C-reactive protein may be obtained but is more valuable as a screening tool to detect CAD rather than guide treatment decisions.

Other Diagnostic Tests

- A 12-lead ECG should be obtained in a patient with symptoms of SIHD. However, it is often normal in patients with SIHD.
- Excercise stress testing is a noninvasive test to detect CAD in patients presenting with symptoms of SIHD.
- Coronary angiography is often performed in patients with a high likelihood of SIHD (eg, "positive" exercise stress test) to detect the presence and extent of CAD.
- Other diagnostic tests may be used in select patients to detect CAD or assess for progression of disease and include myocardial perfusion imaging, cardiac magnetic resonance, "ultra-fast computed tomography (CT)," and CT angiography.

② A thorough patient history is key to the clinical assessment of a patient with SIHD. Exertional chest pain is the classic presenting symptom of patients with SIHD. The differential diagnosis of "chest pain" is broad (Table 33-1). Therefore, it is important to determine if symptoms are due to cardiac or noncardiac pathology. The patient's description of chest pain can be helpful in determining if the pain is more likely SIHD or ACS. The PQRST pneumonic is commonly used when conducting the patient interview to gather important aspects of the chest pain story (Table 33-2).

TABLE 33-1

Differential Diagnosis of Episodic Chest Pain Resembling Angina Pectoris

	Duration	Quality	Provocation	Relief	Location	Comment
Effort angina	5-15 minutes	Visceral (pressure)	During effort or emotion	Rest, nitroglycerin	Substernal, radiates	First episode vivid
Rest angina	5-15 minutes	Visceral (pressure)	Spontaneous	Nitroglycerin	Substernal, radiates	Often nocturnal
Mitral prolapse	Minutes to hours	Superficial (rarely visceral)	Spontaneous (no pattern)	Time	Left anterior	No pattern, variable
Esophageal reflux	10 minutes-1 hour	Visceral	Spontaneous, cold liquids, exercise, lying down	Foods, antacids, H_2 blockers, proton pump inhibitors, nitroglycerin	Substernal, radiates	Mimics angina
Peptic ulcer	Hours	Visceral, burning	Lack of food, “acid” foods	Foods, antacids, H_2 blockers, proton pump inhibitors	Epigastric, substernal	
Biliary disease	Hours	Visceral (wax and wane)	Spontaneous, food	Time, analgesia	Epigastric, radiates	Colic
Cervical disk	Variable (gradually subsides)	Superficial	Spontaneous, food	Time, analgesia	Arm, neck	Not relieved by rest
Hyperventilation	2-3 minutes	Visceral	Emotion, tachypnea	Stimulus removed	Substernal	Facial paresthesia
Musculoskeletal	Variable	Superficial	Movement, palpation	Time, analgesia	Multiple	Tenderness
Pulmonary	Minutes to hours	Visceral (pressure)	Often spontaneous	Rest, time bronchodilator	Substernal	Dyspneic

TABLE 33-2

PQRST Approach to Assessment of a Patient's Chest Pain

Factor	Presentation in Stable Ischemic Heart Disease	Questions to Ask
Precipitating factors	Typically brought on by some level of exercise or exertion	What were you doing when the pain started? What brought on this chest pain?
Palliative measures	Relieved by rest with or without sublingual nitroglycerin in 5-10 minutes	Is there anything that helps the pain go away? If you rest does the pain get better? Does your sublingual nitroglycerin help?
Quality of the pain	Described as a continuous squeezing, heaviness, or tightness	How would you describe the pain? Does the pain change when you breathe in and out?
Region	Substernal	Where is the pain located? Can you point to where the pain seems to originate?
Radiation	Left or right arm, back, down into the abdomen, up into the neck	Does the pain seem to radiate or go to other locations?
Severity	While pain is subjective, those who have pain report a 5 or higher on a 10-point scale	On a scale from 1 to 10, with 1 being no pain, and 10 being the worst pain you have ever had, how would you rate this pain?
Temporal pattern (timing)	Pain lasts less than 20 minutes and is usually relieved in 5-10 minutes	How long did the pain last? How long before the pain went away? After you started to rest, how long before the pain went away?

The chest pain in a patient with SIHD is often precipitated by exertion, such as walking, gardening, sexual activity, or activities of daily living such as showering, cleaning the house, or doing laundry. In this setting, the exertion produces an increase in MVO_2 that exceeds what can be provided by the fixed decrease in myocardial oxygen supply from the obstructive atherosclerotic plaque. Typically, rest or the use of sublingual (SL) nitroglycerin relieves the symptoms. As the patient rests for a few minutes, the HR and BP come down, re-establishing a balance between myocardial oxygen supply and demand, relieving their chest pain. The use of SL nitroglycerin provides acute relief by increasing myocardial oxygen supply through vasodilation of epicardial vessels and a reduction in preload.

Cardiac chest pain is often described as squeezing, crushing, heaviness, or tightness in the chest. It can also be described as numbness or burning in the chest. Chest pain that is described as sharp, increases with inspiration or expiration, or is reproducible with palpation is less likely to be cardiac in origin. The pain is often substernal and may radiate to the right or left shoulder, right or left arm (left more commonly than right), neck, back, or abdomen. Cardiac chest pain rarely radiates above the mandible (jaw) or below the umbilicus (belly button). The severity of cardiac chest pain can be difficult to quantify since pain is subjective, but most patients will state the pain is severe and rate it five or higher on a 10-point scale. The duration of chest pain in patients with SIHD is less than 20 minutes, usually only 5 to 10 minutes. Other symptoms that may be present during times of ischemia include diaphoresis, nausea, vomiting, and dyspnea.

① It is helpful to connect the pathophysiology with the clinical presentation. In SIHD, ischemia is produced by an increase in MVO_2 in the setting of a fixed decrease in supply. The exertion exhausts autoregulation and coronary flow reserve. The patient experiences chest pain. When the patient rests for 5 to 10 minutes or uses an SL nitroglycerin, the MVO_2 decreases to a point in which myocardial supply and demand are back in balance—the pain and other symptoms go away. The major differences between the pain with SIHD compared to ACS would be the precipitating factors and the duration of the chest pain. The patient with an ACS typically has angina at rest that lasts longer than 20 minutes. The pathophysiology in a patient with an ACS is an abrupt decrease in myocardial oxygen supply precipitated by a plaque rupture.

The severity of chest pain and the impact of SIHD on daily activities are often evaluated using the Canadian Cardiovascular Society (CCS) classification system (Table 33-3).[16] The CSS system evaluates the level of activity needed to produce angina. All the current severity scores are limited by the subjective nature of a patient's pain as well as the reliability and reproducibility of patient observations.

TABLE 33-3

Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System

Class	Description of Stage
Class I	Ordinary physical activity does not cause angina, such as walking and climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation
Class II	Slight limitation or ordinary activity. Angina occurs on walking or climbing stairs rapidly, on walking uphill, on walking or stair climbing after meals, in cold, in wind, under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal condition
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking one to two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace
Class IV	Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest

Reproduced from Campeau L. Grading of angina pectoris. *Circulation* 1976;54:522-523.

Not all patients have a typical chest pain presentation.[1] "Typical" angina is comprised of three components: (1) substernal chest discomfort with a characteristic quality and duration, which is (2) provoked by exertion or emotional stress, and (3) relieved by rest or nitroglycerin. Patients with "atypical" angina meet two of the three criteria. Patients meeting one or none of the typical angina characteristics likely have non-cardiac causes of chest pain. Patient groups more likely to present with atypical angina include women and older patients. Patients with DM may also have decreased sensation of pain due to neuropathy.[13] Features of atypical angina or angina equivalents include symptoms such as midepigastric discomfort, effort intolerance, dyspnea, and excessive fatigue. One study found that 65% of women with ischemia present with atypical symptoms.[17]

After a description of the chest pain has been obtained, a review of the patient's CAD risk factors should be performed. Non-modifiable risk factors include the patient's age, sex, and a family history of premature atherosclerotic cardiovascular disease (ASCVD) in first-degree relatives (onset in a male before the age of 55 years or a female before the age of 65 years). Modifiable risk factors including HTN, DM, dyslipidemia, and cigarette smoking should also be explored. In addition to considering traditional risk factors, markers of inflammation, such as high sensitive C-reactive protein, may also be obtained. The evidence regarding the utility of C-reactive protein in the setting of primary prevention is growing but its value in guiding therapy in the setting of established CAD (secondary prevention) is less certain. Due to the systemic nature of atherosclerotic cardiovascular disease (ASCVD), patients with a history of cerebrovascular or peripheral arterial disease are also at high risk for CAD. It is likely that patients who have atherosclerosis in cerebral or peripheral arteries also have atherosclerosis in their coronary arteries even if it has not yet led to episodes of angina.

The physical examination of a patient with SIHD usually produces nonspecific findings. At the time of an angina episode, patients may have tachycardia, diaphoresis, and shortness of breath. Patients may also have symptoms of nausea, vomiting, and lightheadedness. Other physical findings may relate to cardiovascular risk factors including an increased BP or a fourth heart sound reflecting long-standing HTN. Other findings may include pulmonary crackles, a displaced point of maximal impulse, or a third heart sound in patients with HF with reduced ejection fraction (HFrEF).

Diagnostic and Prognostic Testing

Several noninvasive and invasive testing can be done to assist in the diagnosis and evaluation of patients with SIHD. A detailed discussion of these tests and when they should be used can be found in the ACC/AHA SIHD guidelines.[1] More information on how each test is performed is available in Chapter e29, "Evaluation of Cardiovascular Function."

The results of cardiac testing can provide prognostic information, may help guide pharmacotherapy, and identify patients who need a revascularization procedure. All patients with angina symptoms should receive a 12-lead electrocardiogram (ECG). In the resting state, the ECG will be normal in ≥50% of patients with SIHD. In SIHD patients with a normal ECG at rest, about 50% will develop ischemic ST-T wave changes during an episode of angina. These changes can be observed on the ECG conducted during an exercise stress test. Exercise stress testing is a relatively easy and inexpensive method for detecting CAD. Since many patients cannot physically endure an exercise stress test, the myocardium can also be stressed pharmacologically with adenosine, regadenoson, dipyridamole, or dobutamine. Stress testing can provide important diagnostic and prognostic information, especially when conducted with a nuclear imaging study to evaluate myocardial perfusion.

Coronary angiography is the most accurate test for the diagnosis and assessment of patients with CAD and is considered the "gold standard." Unfortunately, coronary angiography is an invasive technique that requires arterial access. Coronary angiography in patients with SIHD routinely reveals that approximately 25% of patients have a single-vessel disease, 25% have double-vessel disease, and 25% have triple-vessel disease, with 5% to 10% presenting with left main coronary disease and another 15% with no detectable critical vessel obstruction.

Coronary angiography is also useful in determining the fractional flow reserve (FFR) in patients with obstructive coronary stenosis. FFR is an indirect index determined by measuring the driving pressure of microcirculatory flow distal to the area of stenosis relative to the coronary driving pressure available in the absence of stenosis.[18] The FFR is attractive for clinical use in that it can immediately assess the physiologic significance of intermediate stenosis to help guide decisions regarding coronary intervention. Moreover, the FFR is unaffected by alterations in resting flow. Data suggest that patients with an FFR of less than or equal to 0.80 may have a better outcome with a revascularization procedure compared to medical therapy, but more studies are needed to determine the best use of this index.[18,19]

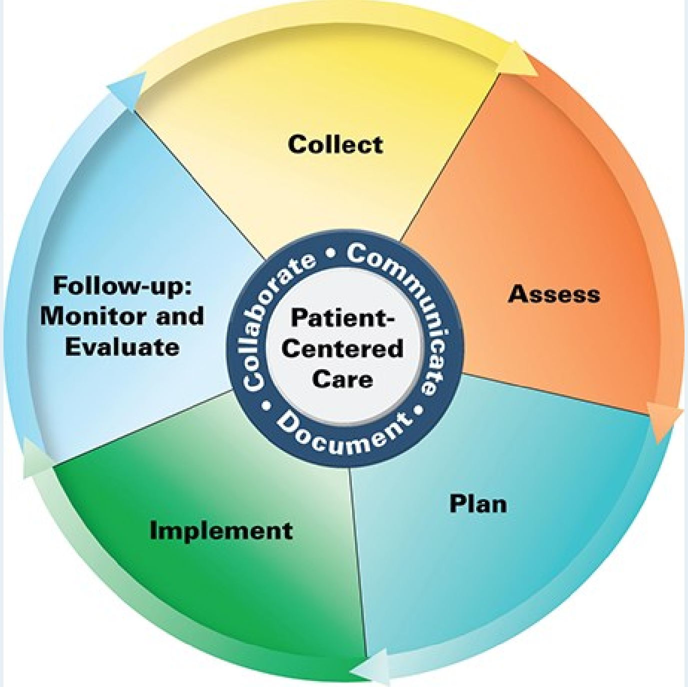
Additional noninvasive diagnostic tests may be used to establish the diagnosis of CAD or follow the progression of disease in patients with SIHD. Myocardial perfusion imaging (eg, nuclear imaging studies) involves the administration of an intravenous radioactive tracer before and after a stressor (exercise or pharmacologic). The uptake of the radioactive tracer is proportional to coronary blood flow in normal myocytes and the resulting images can detect perfusion defects. Cardiac magnetic resonance combined with physiologic or pharmacologic stressors can also detect the presence of perfusion defects as well as wall motion abnormalities. Coronary artery calcium scoring using computed tomography (CT), often called "ultra-fast CT" or electron beam CT, multislice or multidetector CT, and CT angiography can also be used to detect the presence of CAD.

Biomarkers

Cardiac troponin concentrations are released with myocyte death (infarction) and hence are not typically elevated in patients with SIHD. A study of patients undergoing percutaneous coronary intervention (PCI) for the treatment of SIHD found that 6% of patients had an elevated troponin before PCI and these patients were more likely to have an MI or die in-hospital when compared to patients without an elevated troponin (13.4% vs 5.6%).[20] The differences in these outcomes were significant even after 1 year.[20] The study was conducted at multiple sites and, given the lack of a single reference range, no specific troponin value designating increased risk could be determined. The reasons why troponin predicted these outcomes is not completely understood but may be due to increased cardiac cell membrane permeability with repeated ischemia.

PATIENT CARE PROCESS

Patient Care Process for Stable Ischemic Heart Disease (SIHD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Description of chest discomfort and/or related symptoms (eg, precipitating factors, palliative measures, quality, location, radiation, and severity)
- Patient medical (personal and family) and social histories (eg, tobacco/ethanol use), dietary habits (eg, intake of foods high in sodium, cholesterol, and/or saturated fat), and physical activity (eg, frequency and duration of moderate-intensity aerobic activity)
- Current medications including over-the-counter (OTC) medications (eg, aspirin-containing medications), herbals/dietary supplements
- History of allergy or intolerance to previous medications
- Objective data
- Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs: serum creatinine (SCr), potassium (K^+), hemoglobin (Hgb), platelets, liver function tests (LFTs), lipid profile, blood glucose, A1c
    - Diagnostic testing results

Assess

- Description of chest discomfort to determine differential diagnosis and classification of angina symptoms
- Presence of provoking factors (eg, exertion, mental/emotional stress, tachyarrhythmia, high adrenergic state including the use of stimulant medications, and exposure to cold)
- Presence/control of risk factors for SIHD (eg, hypertension, dyslipidemia, diabetes, smoking, and obesity)
- Presence/control of SIHD-related complications (eg, myocardial infarction [MI], heart failure [HF], and stroke)
- Adverse drug reactions from current/previous medications used to treat/prevent angina symptoms or major adverse cardiac events (MACE)

- Previous/recent revascularization procedures (eg, percutaneous coronary intervention [PCI] with/without stenting, and coronary artery bypass graft [CABG] surgery)
- Contraindications to medications to treat/prevent angina symptoms and/or prevent MACE
- Barriers that may impair adherence to the care plan

Plan*

- Initiate/modify drug therapy to treat and prevent angina symptoms, prevent MACE, and address risk factors for SIHD including specific drug(s), dose, route, frequency, and duration (see Fig. 33-2, Tables 32-6 and 32-7)
- Monitoring parameters: efficacy (eg, signs and symptoms of angina and SIHD-related complications) and adverse drug reactions; frequency and timing of follow-up
- Patient education: the purpose of treatment, lifestyle modifications, planned procedures, and drug-specific information (eg, indication, dose, route, frequency, adverse drug reactions; see Table 33-8)
- Self-monitoring for worsening angina symptoms, signs and symptoms of SIHD-related complications, adverse drug reactions, when to seek emergency medical attention
- Address barriers to adherence to medications and lifestyle modification
- Referrals to other providers (eg, primary care provider, endocrinologist, dietician, and smoking cessation)

Implement*

- Provide patient education regarding all elements of the treatment plan as described above
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, every 1-2 months until goals achieved, then every 6-12 months)

Follow-up: Monitor and Evaluate

- Frequency and severity of chest discomfort, sublingual nitroglycerin use, exercise tolerance, presence/control of SIHD risk factors, and presence/control of SIHD-related complications
- Presence of adverse drug reactions and drug-drug interactions
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with the patient, caregivers, and other healthcare professionals.*

TREATMENT

Treatment recommendations from the ACC/AHA guidelines use a Class of Recommendation (COR) system, which estimates the size of the treatment effect, balancing efficacy, and safety. Each recommendation is also based on a Level of Evidence (LOE), which describes the quality, quantity, and consistency of supporting data. Table 33-4 describes the ACC/AHA recommendations and the levels of evidence.[1]

TABLE 33-4

The American College of Cardiology and American Heart Association Evidence Grading System

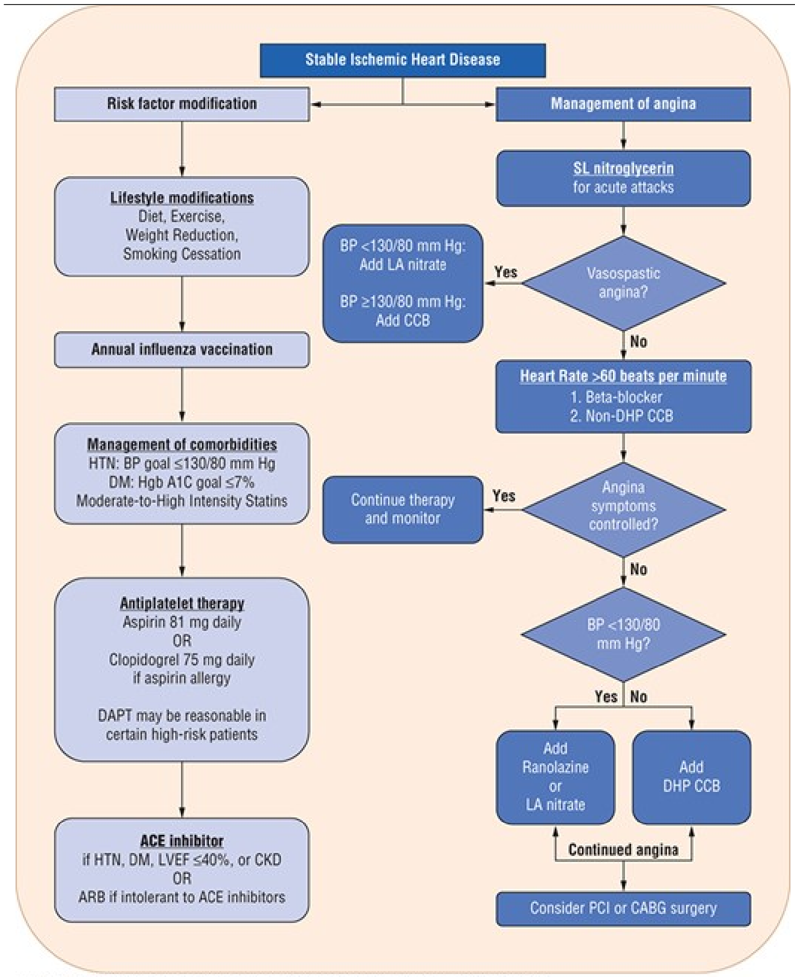
Recommendation Class	Level of Evidence
I. Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective II. Conditions for which there is conflicting evidence or a divergence of opinion that the usefulness/efficacy of a given procedure or treatment is useful and effective a. The weight of evidence/opinion is in favor or usefulness/efficacy b. Usefulness/efficacy is less well established by evidence/opinion III. Conditions for which there is evidence or general agreement that a given procedure or treatment is not useful/effective and in some cases may be harmful	A. Data derived from multiple randomized clinical trials with large numbers of patients B. Data derived from a limited number of randomized trials with small numbers of patients, careful analyses of nonrandomized studies, or observational registries C. Expert consensus was the primary basis for the recommendation

Data from Reference 1.

The treatment of patients with SIHD typically involves two complementary strategies.[1] See Fig. 33-2. The first strategy is directed toward slowing the progression of atherosclerosis and preventing complications such as MI, HF, stroke, and death (either sudden cardiac death or progression of underlying CVD). This strategy focuses on risk-factor modification and providing vasculoprotection therapies (see Table 33-5). While vasculoprotective therapies have demonstrated the ability to reduce mortality, and therefore, the quantity of life, they have minimal impact on improving symptoms and the functional limitations caused by angina, or the quality of life. The second strategy is focused on reducing the number of ischemic episodes as well as increasing the amount of exertion or exercise a patient can accomplish before chest pain occurs (see Table 33-6). Antianginal therapies used to prevent or decrease ischemic episodes rarely have demonstrated a survival benefit but improve quality of life through symptom reduction. Each of the antianginal therapies are relatively equivalent in their ability to reduce ischemic episodes.[21]

FIGURE 33-2

Treatment algorithm for stable ischemic heart disease (guideline-directed medical therapy). The Hgb A1c goal of ≤7% (0.07) is equivalent to 53 mmol/mol. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; CKD, chronic kidney disease; DAPT, dual antiplatelet therapy; DHP, dihydropyridine; DM, diabetes mellitus; HTN, hypertension; LA, long-acting; LVEF, left ventricular ejection fraction).



Stable Ischemic Heart Disease
Risk factor modification
Management of angina
Lifestyle modifications
Diet, Exercise, Weight Reduction, Smoking Cessation
Annual influenza vaccination
Management of comorbidities
HTN: BP goal ≤130/80 mm Hg
DM: Hgb A1C goal ≤7%
Moderate-to-High Intensity Statins
Antiplatelet therapy
Aspirin 81 mg daily
OR
Clopidogrel 75 mg daily if aspirin allergy
DAPT may be reasonable in certain high-risk patients
ACE inhibitor
if HTN, DM, LVEF ≤40%, or CKD
OR
ARB if intolerant to ACE inhibitors
SL nitroglycerin
for acute attacks
Vasospastic angina?
Yes
BP <130/80 mm Hg: Add LA nitrate
BP ≥130/80 mm Hg: Add CCB
No
Heart Rate >60 beats per minute
1. Beta-blocker
2. Non-DHP CCB
Angina symptoms controlled?
Yes
Continue therapy and monitor
No
BP <130/80 mm Hg?
Yes
No
Add Ranolazine or LA nitrate
Add DHP CCB
Continued angina
Consider PCI or CABG surgery

TABLE 33-5

Risk Factor Modification: American College of Cardiology/American Heart Association/American Diabetes Association Recommendations

Lipid Management

Class I

1. Lifestyle modifications, including daily physical activity and weight management, are strongly recommended for all patients with SIHD.
2. Dietary therapy for all patients should include reduced intake of saturated fats (to <7% of total calories), *trans*-fatty acids (to <1% of total calories), and cholesterol (to <200 mg/day).
3. In addition to therapeutic lifestyle changes, a high-intensity statin should be prescribed with a goal of achieving a ≥ 50% decrease in LDL-C, in the absence of contraindications or documented adverse drug reactions.
4. In patients with contraindications or intolerant to high-intensity statin therapy, moderate-intensity statins should be used, if tolerated, with a goal of achieving a 30%-49% decrease in LDL-C.

Class IIa

1. In patients older than 75 years, moderate- or high-intensity statin therapy should be used after considering the potential benefits (risk reduction) and risks (adverse drug reactions, drug-drug interactions, patient frailty).
2. For patients with an LDL-C >70 mg/dL (1.81 mmol/L) on maximally tolerated statin therapy and at very high risk for CV events, the addition of ezetimibe

is reasonable.

3. For patients with an LDL-C >70 mg/dL (1.81 mmol/L) or a non-HDL-C level ≥ 100 mg/dL (≥ 2.59 mmol/L) on maximally tolerated LDL-C lowering therapy (statin plus ezetimibe) and at very high risk for CV events, the addition of a PCSK-9 inhibitor is reasonable depending on benefit, risk, cost, and patient preference.
4. In patients older than 75 years, moderate- or high-intensity statin therapy should be used after considering the potential benefits (risk reduction) and risks (adverse drug reactions, drug-drug interactions, patient frailty).

Blood Pressure Management

Class I

1. All patients should be counseled about the need for lifestyle modification: weight control; increased physical activity; alcohol moderation; sodium reduction; and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products.
2. In patients with SIHD with BP 130/80 mm Hg or higher, antihypertensive drug therapy should be instituted in addition to or after a trial of lifestyle modifications.
3. The specific medications used for the treatment of HTN in SIHD patients should be based on compelling indications (eg, prior MI, angina, and HFrEF) and may include β-blockers, ACE inhibitors, or ARBs with the addition of other drugs, such as thiazide diuretics, dihydropyridine calcium channel blockers, or aldosterone antagonists, if needed to achieve a goal of BP less than 130/80 mm Hg.
4. For patients with angina and persistent uncontrolled HTN, it is recommended to add dihydropyridine CCBs to β-blockers.

Class IIa

1. For patients who have had an ACS, it is reasonable to continue β-blockers long-term if needed for treatment of HTN.

Diabetes Management

Class I*

1. Among patients with type 2 DM who have established ASCVD or indicators of high-risk, established kidney disease, or HF, a sodium-glucose cotransporter 2 (SGLT2) inhibitor or glucagon-like peptide 1 (GLP-1) receptor agonist with demonstrated CVD benefit is recommended as part of the glucose-lowering regimen independent of A1c, metformin use, and in consideration of patient-specific factors.

Class IIa

1. For selected individual patients, such as those with a short duration of diabetes mellitus and a long life expectancy, a goal A1c of 7% (0.07; 53 mmol/mol) or less is reasonable.
2. A goal A1c <8% (0.08; 64 mmol/mol) is reasonable for certain patients according to age, history of hypoglycemia, the presence of microvascular or macrovascular complications, or presence of coexisting medical conditions.

Class IIb

1. Initiation of pharmacotherapy interventions to achieve target A1c might be reasonable.

Influenza Vaccination

Class I

1. Annual influenza vaccinations are recommended for patients with SIHD.

Physical Activity

Class I

1. For all patients, the clinician should encourage 30-60 minutes of moderate-intensity aerobic activity, such as brisk walking, at least 5 days and preferably 7 days per week, supplemented by an increase in daily lifestyle activities (eg, walking breaks at work, gardening, and household work) to improve cardiorespiratory fitness and move patients out of the least-fit, least-active, high-risk cohort (bottom 20%).
2. For all patients, risk assessment with a physical activity history and/or an exercise test is recommended to guide prognosis and prescription.
3. Medically supervised programs (cardiac rehabilitation) and physician-directed, home-based programs are recommended for at-risk patients at first diagnosis.

Class IIa

1. It is reasonable for the clinician to recommend complementary resistance training at least 2 days per week.

Weight Management

Class I

1. BMI and/or waist circumference should be assessed at every visit, and the clinician should consistently encourage weight maintenance or reduction through an appropriate balance of lifestyle, physical activity, structured exercise, caloric intake, and formal behavioral programs when indicated to maintain or achieve a BMI between 18.5 and 24.9 kg/m^2 and a waist circumference less than 102 cm (40 in.) in men and less than 88 cm (35 in.) in women (less for certain racial groups).
2. The initial goal of weight loss therapy should be to reduce body weight by approximately 5%-10% from baseline. With success, further weight loss can be attempted if indicated.

Smoking Cessation Counseling

Class I

1. Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged for all patients with SIHD. Follow-up, referral to special programs, and pharmacotherapy are recommended along with a systematic strategy for smoking cessation (Ask, Advise, Assess, Assist, Arrange, Avoid).

Management of Psychological Factors

Class IIa

1. It is reasonable to consider screening SIHD patients for depression and to refer or treat when indicated.

Class IIb

1. Treatment of depression has not been shown to improve cardiovascular disease outcomes but might be reasonable for its other clinical benefits.

Alcohol Consumption

Class IIb
1. In patients with SIHD who use alcohol, it might be reasonable for nonpregnant women to have one drink (4 ounces [~120 mL] of wine, 12 ounces [355 mL] of beer, or 1 ounce [30 mL] of spirits) a day and for men to have one or two drinks per day unless alcohol is contraindicated (such as in patients with a history of alcohol abuse or dependence or with liver disease).
Avoiding Exposure to Air Pollution
Class IIa
1. It is reasonable for patients with SIHD to avoid exposure to increased air pollution to reduce the risk of cardiovascular events.

*American Diabetes Association Standards of Medical Care in Diabetes recommendation is A: clear evidence from well-conducted, generalizable randomized controlled trials that are adequately powered.[24] This recommendation was considered equivalent to a Class I recommendation by the American College of Cardiology/American Heart Association.

Data from References 1,22–24.

TABLE 33-6

American College of Cardiology/American Heart Association Class of Recommendations for Pharmacotherapy to Relieve Symptoms

Class I
1. β-blockers should be prescribed as initial therapy for the relief of symptoms in patients with SIHD (LOE B). 2. Calcium channel blockers or long-acting nitrates should be prescribed for the relief of symptoms when β-blockers are contraindicated or cause unacceptable adverse drug reactions in patients with SIHD (LOE B). 3. Calcium channel blockers or long-acting nitrates, in combination with β-blockers, should be prescribed for the relief of symptoms when initial treatment with β-blockers is unsuccessful in patients with SIHD (LOE B). 4. Sublingual nitroglycerin or nitroglycerin spray is recommended for the immediate relief of angina in patients with SIHD (LOE B).
Class IIa
1. Treatment with a long-acting non-dihydropyridine calcium channel blocker (verapamil or diltiazem) instead of a β-blocker as initial therapy for relief of symptoms is reasonable in patients with SIHD (LOE B). 2. Ranolazine can be useful when prescribed as a substitute for β-blockers for the relief of symptoms in patients with SIHD if initial treatment with β-blockers leads to unacceptable adverse drug reactions or is ineffective or if initial treatment with β-blockers is contraindicated (LOE B). 3. Ranolazine in combination with β-blockers can be useful when prescribed for relief of symptoms when initial treatment with β-blockers is not successful in patients with SIHD (LOE A).

Data from Reference 1.

Desired Outcomes

④ In addition to reducing the risk of CV events and mortality, the ACC/AHA SIHD guidelines state that a goal of therapy should be the complete, or nearly complete, elimination of chest pain and return to normal activities with a functional capacity of CCS class I angina.[1]

Pharmacologic Therapy

Providing guideline-directed medical therapy (GDMT), also referred to as optimal medical therapy, reduces the risk of mortality in patients with SIHD.[1] In the absence of proximal CAD, multivessel CAD, or acute ischemia, GDMT reduces the rate of death and MI similar to revascularization therapy for most patients with SIHD. Most of the evidence-based GDMT target risk-factor modification (Table 33-5), but also include aspirin and angiotensin-converting enzyme (ACE) inhibition.

Antithrombotic Therapy

⑤ Aspirin produces an antiplatelet effect by irreversibly blocking cyclooxygenase-1 (COX-1) activity (~95%) for the life of the platelet, thereby inhibiting thromboxane A_2 production. The reduction in thromboxane A_2 leads to reduced platelet activation and aggregation. Aspirin doses as small as 30 mg daily effectively inhibit COX-1. Aspirin doses above 75 to 100 mg provide little additional antiplatelet activity.[25] Aspirin may also provide benefits through some non-platelet-mediated effects. Higher doses of aspirin (≥325 mg daily) significantly impair endothelial secretion of prostacyclin, which is a natural vasodilator. Low-dose aspirin does not have this deleterious effect. Although aspirin may inhibit prostacyclin secretion, the effects on the endothelium are reversible, unlike its effect on platelets.[26] After unbound aspirin has been removed from the circulation (half-life is about 30 minutes), prostacyclin secretion and its vasodilation effects are restored. Aspirin may also attenuate the synthesis of cytokines such as interleukin-2, interleukin-6, and interferon in leukocytes as well as prevent leukocyte rolling and macrophage-induced endothelial activation.[26] The extent to which these pharmacologic properties contribute to the clinical benefits of aspirin is unknown.

Evidence supporting the effectiveness of aspirin in patients with SIHD first came from a subgroup analysis of the Physicians Health Study.[27] Patients with SIHD who took aspirin (325 mg every other day) had an 87% reduction in first MI compared to placebo. This benefit came with a significant increase in hemorrhagic stroke, although none of the strokes were fatal. These beneficial effects were confirmed in the more robust Swedish Angina Pectoris Aspirin Trial.[28] Patients with controlled angina on sotalol treated with 75 mg of aspirin daily had a 34% reduction in first MI or sudden death compared to placebo. There was no difference in major bleeding or stroke between the groups.

Some patients are nonresponsive to the antiplatelet effects of aspirin, and therefore, do not receive a clinical benefit. In patients with CAD, the risk of recurrent CV events was more than threefold higher in patients with aspirin non-responsiveness.[29] The rate of aspirin non-responsiveness was estimated to be 24% in one meta-analysis, but the range reported in the included studies was wide (0%-57%).[30] In studies that used light transmission aggregotomy induced with arachidonic acid (the gold standard test) or measured serum thromboxane B_2, the rate of aspirin non-responsiveness was only 6%.[30] These results are similar to the findings of the Aspirin-Induced Platelet Effects (ASPECT) trial, in which aspirin non-responsiveness defined by COX-1-nonspecific methods was 27%, compared to only 6% when COX-1-specific methods were used.[31] The ASPECT investigators also reported no difference in aspirin non-responsiveness between patients receiving 81, 162, or 325 mg daily.[31] A lack of dose-response is consistent with the findings of the Antithrombotic Trialists' Collaboration meta-analysis which demonstrated a similar reduction in vascular events regardless if patients were receiving low dose (75-150 mg daily), moderate dose (160-325 mg daily), or high dose (500-1500 mg daily) aspirin.[25]

Aspirin non-responsiveness may occur because of changes to the COX-1 enzyme, such as changes to the enzyme structure, or temporary blockade of the active site on the enzyme. Of particular concern is the potential for non-steroidal anti-inflammatory drug (NSAID) therapy to block the COX-1 enzyme. Naproxen and ibuprofen have been shown to interfere with aspirin's antiplatelet effect when co-administered by competing for the site of action.[26] The timing of coadministration appears to be an important factor. The effect of aspirin on platelet aggregation is impaired when ibuprofen is given 2 hours before aspirin, but when aspirin is given first, antiplatelet activity is retained.

While aspirin non-responsiveness does exist, the incidence is probably not as high as once believed. Although patients with aspirin non-responsiveness are more likely to have ischemic events, routinely testing patients is not recommended. Given that increasing the dose of aspirin does not impact responsiveness or improve clinical outcomes, the only effective strategy would be to change to or add an alternative antiplatelet agent.

For patients unable to take aspirin due to allergy or intolerance, clopidogrel represents a suitable alternative antiplatelet agent to prevent MI and death in patients with CAD.[1] While clopidogrel significantly reduced the incidence of stroke, MI, or vascular death in patients with ASCVD compared to aspirin in the The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events trial, the absolute difference between the two strategies was small (0.5%;

number needed to treat = 200).[26] Given the small magnitude of benefit and potential for non-responsiveness to clopidogrel, it remains a second-line choice in patients with CAD. When used in patients with SIHD, clopidogrel should be given 75 mg daily.

Dual antiplatelet therapy (DAPT) with aspirin plus a $P2Y_{12}$ inhibitor, such as clopidogrel, has a clear benefit in patients after a PCI with coronary stent placement and following treatment for ACS. The combination of aspirin plus clopidogrel for 28 months did not reduce the risk of death, MI, stroke, or coronary revascularization when compared to aspirin alone but increased the risk of moderate bleeding.[32] However, in those patients with established vascular disease at study entry receiving aspirin plus clopidogrel, there was a significant reduction in the risk of death, MI, and stroke compared to aspirin alone (7.3% vs 8.8%).[32] In patients with a history of MI at least 1 year prior, the combination of ticagrelor 60 mg twice daily plus aspirin reduced the risk of cardiac events compared to aspirin alone but more than doubled the risk of major bleeding complications.[32] This dose of ticagrelor plus aspirin was evaluated in patients with both SIHD and type 2 DM. Although a significant reduction in CV death, MI, and stroke was observed with a similar increase in major bleeding in the overall study population, the benefit was greatest in patients with a previous PCI and may be considered in this setting.[32]

Patient responsiveness to clopidogrel is highly variable and the antiplatelet activity follows a bell-shaped curve.[33] Several tests have been used to evaluate clopidogrel's antiplatelet activity and there are different definitions of non-responsiveness. Thus, estimates of non-responsiveness to clopidogrel range from 5% to 44%.[34,35] Several trials have correlated clopidogrel non-responsiveness with poor clinical outcomes.

It is unclear what to do if a patient is found to have a lack of appropriate response to clopidogrel. The most common cause of non-responsiveness is poor adherence. Even a small number of missed doses will result in an inadequate response to clopidogrel. Data from a large registry provides evidence that poor adherence is associated with increased ischemic events, as well as important insight into patient predictors of poor adherence.[36] Lack of response may also be due to polymorphisms in cytochrome P450 2C19, which is responsible for the conversion of clopidogrel into its active compound.[37] There may also be drug interactions with the cytochrome P450 2C19, such as proton pump inhibitors, that may alter clopidogrel's effectiveness. A more detailed discussion on the clinical impact of these polymorphisms and drug interactions can be found in Chapter 34 (Acute Coronary Syndrome).

Rivaroxaban, a direct factor Xa anticoagulant, has demonstrated benefit in patients with CAD when added to aspirin therapy. In a large, randomized trial, rivaroxaban 2.5 mg twice daily added to low-dose aspirin provided a 24% relative reduction in CV death, MI, and stroke compared to low-dose aspirin alone.[38] Although there was also a significant increase in major bleeding with patients receiving rivaroxaban, 75% of the major bleeding events would not have been considered a major bleed by standard bleeding definitions. Patients with polyvascular disease, heart failure, diabetes mellitus, or at least moderate renal insufficiency seemed to obtain the most benefit from the addition of rivaroxaban to aspirin therapy.[39]

Recommendations from the ACC/AHA for the use of antiplatelet agents in the management of SIHD include a Class I recommendation for the use of aspirin 75 to 162 mg daily.[1] Aspirin should be continued indefinitely in the absence of contraindications (LOE A). Clopidogrel is considered an appropriate alternative when aspirin is contraindicated (LOE B). The guidelines state that treatment with aspirin (75-162 mg daily) and clopidogrel 75 mg daily might be reasonable in certain high-risk patients with SIHD (Class IIb, LOE B recommendation). Data supporting the combination of rivaroxaban and aspirin in patients with SIHD were not available when the ACC/AHA guidelines were published. However, this combination is recommended by the American Diabetes Association.[24]

ACE Inhibitors

⑥ In the setting of ASCVD, ACE inhibitors stabilize coronary plaque, provide restoration or improvement in endothelial function, inhibit vascular smooth muscle cell growth, decrease macrophage migration, and possibly prevent oxidative stress. They may also possess some antithrombotic properties by inhibiting platelet aggregation and augmenting the endogenous fibrinolytic system. However, ACE inhibitors have not been shown to improve symptomatic ischemia or chest pain episodes.[40]

The role of ACE inhibitors in patients at high risk for CV events was evaluated in the HOPE (Heart Outcomes Prevention Evaluation) trial.[41] Patients with normal LV function and either ASCVD (history of CAD [~80% of patients, including 55% with SIHD], stroke, peripheral arterial disease) or its equivalent (eg, DM with at least one additional risk factor) treated with ramipril 10 mg daily were significantly less likely to experience one of the primary endpoints (CV death, MI, or stroke) compared to placebo. These impressive benefits were seen despite a minimal reduction in BP with the use of ramipril. Benefits were consistent across all groups of patients enrolled, regardless of the location of ASCVD.

Subsequent trials have produced conflicting results. One trial using perindopril 8 mg daily significantly reduced the incidence of CV death, MI, or cardiac arrest compared to placebo in patients with SIHD.[42] In contrast, the addition of trandolapril 4 mg daily to standard therapy in patients with documented CAD did not significantly reduce the incidence of CV death, MI, or coronary revascularization in another trial.[43] A meta-analysis of seven trials with 33,960 patients demonstrated a significant 14% reduction in mortality in patients with CAD treated with an ACE inhibitor.[44] Based on the well-established benefits, it is appropriate to use ACE inhibitors in patients with SIHD who have HTN, DM, HFrEF, or following an MI.[1]

Trials have evaluated the role of angiotensin receptor blockers (ARB) to determine if they provide a similar benefit as ACE inhibitors in the setting of CAD. A trial in patients with pre-existing CVD or DM with end-organ damage treated with either the ACE inhibitor ramipril 10 mg daily or the ARB telmisartan 80 mg daily appeared to have a similar benefit.[45] However, there was no added benefit from combining the two agents. There were significantly more episodes of hypotension, syncope, and renal dysfunction in patients treated with combination therapy. In a second trial, telmisartan failed to demonstrate a CV benefit over placebo in patients who were intolerant to ACE inhibitors.[46] Based on these conflicting data, an ARB may be considered if the patient cannot tolerate ACE inhibitor therapy, and combination therapy should be avoided.

Recommendations from the ACC/AHA include a Class I recommendation to use ACE inhibitors in all patients with SIHD who also have HTN, DM, HFrEF, or chronic kidney disease, unless contraindicated (LOE A).[1] ARBs are recommended for the same patient populations if they are intolerant to ACE inhibitors (LOE A). It is a Class IIa recommendation to use ACE inhibitors in patients with both SIHD and other vascular diseases (LOE B), and ARBs in these patients if intolerant to ACE inhibitors (LOE B).

Lipid Management

⑦ Multiple studies have demonstrated a continuous increase in coronary events with increasing low-density lipoprotein cholesterol (LDL-C) in men and women with and without SIHD. Statin therapy significantly lowers LDL-C and reduces CV event rates. The Cholesterol Treatment Trialist Collaborators found a 10% reduction in all-cause mortality and a 20% reduction in cardiac mortality for every 40 mg/dL (1.03 mmol/L) reduction in LDL-C.[47] Statin therapy also reduces the risk of MI, stroke, and the need for coronary revascularization. Higher dose and high potency statin regimens are more effective than lower dose, low-potency regimens.[47]

Current guidelines recommend that all patients with known ASCVD, such as SIHD, should receive high-intensity statin therapy to achieve a 50% or more reduction in LDL-C.[23] Patients over the age of 75 years and those who cannot tolerate high-intensity statin therapy should receive moderate-intensity statin therapy to achieve a 30% to 49% reduction in LDL-C. In patients with clinical ASCVD who do not achieve a 50% reduction in LDL-C or who have an LDL ≥70 mg/dL (1.81 mmol/L) on maximally tolerated high-intensity statin therapy, the additional non-statin therapies such as ezetimibe, PCSK9-inhibitors, or bile-acid sequestrates may be considered.[23] In patients with clinical ASCVD with DM, a recent ASCVD event, CKD, or poorly controlled risk factors, targeting an LDL-C less than 70 mg/dL (1.81 mmol/L) or non–HDL-C less than 100 mg/dL (2.59 mmol/L) may be considered.[23]

High-intensity statin options include atorvastatin 40 or 80 mg daily or rosuvastatin 20 or 40 mg daily. Atorvastatin 80 mg is the preferred dose. The 40 mg dose of atorvastatin was only used in one trial in patients who could not tolerate the 80 mg dose.[48] Also, rosuvastatin 20 mg daily is the preferred regimen based on the trial evidence, with the 40 mg daily dose being recommended because it is also an approved dose.[23] Moderate-intensity statin regimens include once-daily atorvastatin 10 to 20 mg, rosuvastatin 5 to 10 mg, simvastatin 20 to 40 mg, pravastatin 40 to 80 mg, lovastatin 40 to 80 mg, pitavastatin 1 to 4 mg, fluvastatin extended-release 80 mg, or twice daily fluvastatin 40 mg.[23]

Regular physical activity, dietary changes, and weight management should also be implemented (Table 33-8). Dietary approaches to lowering LDL-C include replacing saturated and *trans* fatty acids with dietary carbohydrates or unsaturated fatty acids and reducing dietary cholesterol. A diet low in saturated fat and cholesterol typically lowers LDL-C by 10% to 15%. The addition of plant stanols/sterols (2g/d) can lower LDL-C by 5% to 15%. Viscous fiber (>10 g/d) reduces LDL-C by 3% to 5%. A 10 lb (4.5 kg) weight loss reduces LDL-C by 5% to 8%. Regular physical exercise improves cardiac fitness and facilitates weight loss but does not reliably lower LDL-C.

Blood Pressure Management

A number of observational trials have demonstrated a continuous relationship between BP and the risk of CV events. The risk of vascular death increases linearly over the BP range of 115/75 mm Hg to 185/115 mm Hg. The risk doubles for every 20 mm Hg increase in systolic BP or 10 mm Hg increase in diastolic BP.[22] Clinical trials have evaluated when to initiate therapy and attempted to define the target BP goal for patients with HTN. However, the specific BP target for patients with and without SIHD has been debated. Clinical trials and meta-analyses support the current guidelines which recommend initiating pharmacotherapy in patients with SIHD with a BP of 130/80 mm Hg or higher and treating to a BP goal of less than 130/80 mm Hg.[22,49,50]

Optimal BP should be achieved using lifestyle modifications as well as pharmacotherapy (Table 33-5). This includes a diet rich in fruits, vegetables, and low-fat dairy products, regular physical exercise, a reduction in dietary sodium, and limited alcohol consumption. Lifestyle modifications can also contribute to weight loss. A 10 kg weight loss can reduce systolic BP by 5 to 20 mm Hg.

Drugs used to treat HTN in patients with SIHD commonly include agents that can be used to treat the symptoms of the disease. β-blockers are often used to control angina symptoms and they also lower BP. Patients may also be on ACE inhibitors to reduce CV risk. Therefore, most patients with SIHD will receive these two classes of agents for the treatment of HTN. If additional therapy is needed, dihydropyridine (DHP) calcium channel blockers (CCBs) are often added because they treat both HTN and reduce angina symptoms. If the patient's angina symptoms are well controlled, thiazide diuretics may be considered as add-on therapy for HTN. They are considered a first-line treatment in most populations and do not appear to be detrimental when used by patients with SIHD.[22]

Smoking Cessation

The relationship between tobacco use and increased risk of CVD is well documented.[51] Cigarette smoking promotes and accelerates ASCVD through a number of mechanisms including increased platelet adhesion, elevated fibrinogen concentrations, endothelial dysfunction, altered serum lipids, and vasoconstriction.[52] Smoking is perhaps the most important cause of preventable CVD and death.[51] Compared to those who never smoked, smokers lose approximately 10 years of life expectancy and early cessation is associated with an approximately 90% reduction in mortality and improved quality of life.[53] Therefore, abstinence and smoking cessation are key components of lifestyle modifications for patients with SIHD.

Advice from a clinician recommending and discussing the importance of smoking cessation significantly increases the likelihood that a patient will quit. Clinicians should approach smoking cessation by using the 6 A's framework:[1]

1. Ask each patient about tobacco use at every visit
2. Advise each smoker to quit
3. Assess each smoker's willingness to make a quit attempt
4. Assist each smoker in making a quit attempt by offering medication and referral for counseling
5. Arrange for follow-up
6. Avoid exposure to environmental tobacco smoke

Several pharmacologic agents are available over the counter or with a prescription and are all more effective than placebo.[54] Nicotine replacement therapy is available in a number of dosage forms without a prescription to fit the patient's lifestyle including patches, tablets, gum, lozenges, and nasal spray. Sustained-release bupropion and the partial agonist of the $\alpha_4\beta_2$ nicotinic receptor, varenicline, are also first-line medications to treat tobacco dependence in adults. In one study, no evidence of serious CVD or CV adverse events occurred in patients receiving smoking cessation medications, demonstrating all three pharmacotherapies are safe from a cardiovascular standpoint.[55] Nonpharmacologic methods for smoking cessation are just as important as pharmacotherapy. Self-help programs, telephone counseling, behavioral therapy, and exercise all can be used to help patients quit smoking.

Diabetes Management

8 DM is a strong risk factor for the development of CVD. Patients with type 1 DM have a 10-fold increased risk of having a CV event and patients with type 2 DM have a two- to sixfold risk of CV death compared to those without DM.

Like HTN, the glycemic target for patients with DM, including those with SIHD, is the subject of considerable debate. Studies have found that achieving an A1c of less than 7% (0.07; 53 mmol/mol) reduces microvascular complications from DM such as retinopathy, nephropathy, and neuropathy.[56] While subgroup analyses of larger trials have suggested lower rates of ischemic events in patients randomized to intensive glycemic control (A1c less than 7% [0.07; 53 mmol/mol]), macrovascular events were not significantly reduced in trials comparing intensive to more lenient glycemic control in high-risk patients with DM, including those with pre-existing CVD.[56] In these trials, patients in the intensive glycemic control groups had higher rates of adverse events including severe hypoglycemia, CVD death, and overall mortality.[56] In patients with SIHD, current AHA/ACC recommendations target an A1c of less than 7% (0.07; 53 mmol/mol) for patients with DM of short duration and a long life expectancy (Class IIa, LOE B) but a more lenient goal (A1c <8% [0.08; 64 mmol/mol]) for frail or high-risk patients (Class IIa, LOE C; Table 33-5).[1]

Metformin is the drug of first choice for the treatment of type 2 DM, including patients with SIHD. While sulfonylureas provide a similar reduction in A1c, their potential to induce hypoglycemia and weight gain make metformin a more attractive option. Although debate remains regarding the effect of metformin and sulfonylureas on CV events, a recent meta-analysis did not find a significant association between the use of either therapy and CV outcomes.[56] Some newer therapies for the treatment of type 2 DM significantly reduce the risk of CV events, including all-cause mortality.[57] In a recent meta-analysis, the risk of death was reduced by 20% (hazard ratio [HR] 0.80, 95% credible interval [CrI] 0.71-0.89) in patients treated with sodium-glucose-cotransporter 2 (SGLT-2) inhibitors and by 12% (HR 0.88, 95% CrI 0.81-0.94) in patients treated with glucagon-like peptide 1 (GLP-1) agonists compared to patients treated with standard therapies in the control groups.[58] Cardiovascular mortality was also lower in patients treated with either SGLT-2 inhibitors or GLP-1 agonists compared to control subjects.[58] The risk of adverse event rates leading to discontinuation was higher with GLP-1 agonists compared to SGLT-2 inhibitors and dipeptidyl peptidase 4 inhibitors.[58] Consequently, updated guidelines for the treatment of DM now recommend using agents that have been shown to reduce CV events (eg, empagliflozin, canagliflozin, and liraglutide) as part of the glucose-lowering regimen, regardless of the patient's current glycemic control and should be added to metformin therapy in patients with DM type 2 and ASCVD[24]

Influenza Vaccination

Patients with cardiac disease who develop seasonal influenza are at high risk for complications and more likely to die. In patients with CAD, influenza vaccination has been associated with lower rates of ischemic events, although the benefit may be greatest in those with a recent ACS prior to vaccination.[59,60] Current guidelines recommend that all patients with SIHD should receive an annual influenza vaccination to prevent morbidity and mortality.[1]

Pharmacotherapy to Reduce Symptoms

β-Blockers

9 β-Adrenergic blocking agents are commonly used in the management of patients with SIHD and reduce both symptomatic and silent episodes of myocardial ischemia. β-Adrenergic blocking agents competitively inhibit the effects of circulating catecholamines on β-adrenoceptors. The predominant adrenergic receptor type in the heart is the β_1-receptor, and competitive blockade minimizes the influence of endogenous catecholamines on the chronotropic and inotropic state of the myocardium. β-Blockers also produce a reduction in BP through competitive inhibition of β_1-receptors in the kidney, leading to a reduction in renin release. By reducing HR, myocardial contractility, and intramyocardial wall tension through BP reduction, β-blockers impact all major contributing factors to MVO_2.[61] Reductions in HR may also improve myocardial oxygen delivery by prolonging diastole filling time and increasing myocardial perfusion.

β_1-Selectivity does not improve the efficacy of β-blockers for the treatment of SIHD and all agents appear equally effective. β_1-Selective agents would be preferred in patients with chronic obstructive pulmonary disease, peripheral arterial disease, DM, dyslipidemias, and sexual dysfunction, where blocking β_2-adrenergic receptors may be problematic. It should be noted that even β_1-selective agents lose their selectivity at higher doses. β-Blockers with combined α_1 and β-blockade are also effective in the management of angina. β-Blockers with intrinsic sympathomimetic activity cause a slight-to-moderate activation of the β-receptor, in addition to competing with endogenous catecholamines. Due to this unique pharmacologic property, they do not affect resting HR but do modestly lower HR when catecholamine concentrations are increased during exercise. While agents with intrinsic sympathomimetic activity may be useful for patients with peripheral arterial disease and dyslipidemia, they are not preferred in patients with CAD. The selection of a β-blocker in patients with SIHD should be guided by the presence of comorbid diseases, preferred dosing frequency, and cost.

Most adverse drug reactions experienced with the use of β-blockers are an extension of their pharmacologic activity. Patients receiving β-blockers may experience bradycardia, hypotension, heart block, impaired glucose metabolism, and altered serum lipids. β-Blockers may alter the lipid profile by increasing triglycerides and decreasing HDL-C. They have no impact on LDL-C. Changes in the lipid profile are greater with non-selective β-blockers and are usually transient. Central nervous system adverse drug reactions such as fatigue, depression, insomnia, and general malaise are usually mild but among the most common reasons for treatment discontinuation. Impotence has been reported in approximately 1% of men receiving β-blockers. Patients with a history of airway disease may suffer from bronchospasm and patients with HFrEF may become fluid overloaded. Patients without these pre-existing disease states usually do not suffer from these adverse drug reactions and it is important to note that even patients at risk for adverse drug reactions receive significant benefit from the use of β-blockers. β-Blockers are absolutely contraindicated in patients with pre-existing bradycardia, second or third-degree atrioventricular block, a history of uncontrolled reactive airway disease (asthma), severe peripheral arterial disease (critical limb ischemia), hypotension, HFrEF with unstable fluid status, and patients with DM who have frequent episodes of hypoglycemia. All patients should receive a β-blocker following an MI unless there is an absolute contraindication. A patient with SIHD who has never had an ACS, especially acute MI, and who has concurrent chronic obstructive pulmonary disease (COPD) may be treated with a cardioselective β-blocker if there are compelling reasons to use a β-blocker over another antianginal medication. However, in patients with moderate to severe COPD, β-blockers may increase the risk COPD-related hospitalizations.[62]

If β-blocker therapy needs to be discontinued, doses need to be tapered over 2 to 3 weeks to prevent abrupt withdrawal. During β-blocker therapy, β-receptors become up-regulated in the myocardium. After an abrupt withdrawal of β-blocker therapy, these new receptors, along with all of the blocked receptors, are now stimulated by endogenous catecholamines. This can produce a significant increase in MVO_2, induce ischemia, and even MI. If for some reason β-blockers cannot be tapered, patients should be instructed to avoid exertion as much as possible and manage angina episodes with SL nitroglycerin. Using a non-DHP CCB would be the preferred second-line choice if β-blockers are contraindicated or must be discontinued.

Calcium Channel Blockers

⑦ CCBs effectively reduce the frequency and duration of angina episodes in patients with SIHD. All CCBs reduce MVO_2, as well as provide some increase in supply by inducing coronary vasodilation and preventing vasospasm. CCBs modulate calcium entry into the myocardium and vascular smooth muscle, as well as other tissues. This leads to a reduction in the cytosolic concentration of calcium responsible for activation of the actin-myosin complex leading to the contraction of vascular smooth muscle and myocardium.

CCBs should be considered as two separate classes of drugs. While all CCBs inhibit the influx of calcium ions, the location of the inhibition differs based on the chemical structure of the agents. The DHP CCBs, such as nifedipine, amlodipine, isradipine, and felodipine, primarily block calcium receptors in vascular smooth muscle cells, such as arterioles, with minimal effect on the myocardium. In contrast, the phenylalkylamine (verapamil) and benzothiazepine (diltiazem) agents, commonly referred to as non-DHP CCBs, block calcium ion entry mostly in the myocardium, with minimal effect on vascular smooth muscle. Verapamil has the greatest impact on myocardial calcium channels with diltiazem having an intermediate effect.

All CCBs reduce MVO_2 by reducing wall tension by lowering arterial blood pressure, and to a minor extent, depressing cardiac contractility. Like β-blockers, non-DHP CCBs also reduce HR and contractility through blockade of myocardial calcium channels. The DHP CCBs slightly reduce cardiac contractility and produce either a neutral or increase in HR due to potential reflex tachycardia from direct arterial dilation. The effect on contractility and reflex tachycardia is not uniform across the class of DHP CCBs. Agents such as nifedipine produce more impairment of LV function than amlodipine and felodipine. Due to their potential to cause reflex tachycardia, short-acting DHP CCBs should be avoided when treating SIHD, chronic HTN, hypertensive crisis, or during an ACS event. Reflex tachycardia from longer-acting DHP CCBs can be prevented with concurrent β-blocker therapy.

Common adverse drug reactions of CCBs vary between the two classes. Patients taking non-DHP CCBs may experience bradycardia, hypotension, atrioventricular block, and symptoms of LV depression. Non-DHP CCBs should not be used in patients who have contraindications or cannot tolerate the rate-slowing effects of β-blockers due to their similar pharmacodynamic effects. Non-DHP CCBs should be avoided in patients with concomitant HFrEF due to their negative inotropic effects but can provide benefit to patients in atrial fibrillation with a rapid ventricular response due to their negative dromotropic effects. Verapamil has also been reported to cause constipation in up to 8% of patients. Patients taking DHP CCBs may experience reflex tachycardia, hypotension, headache, gingival hyperplasia, and peripheral edema. While most DHP CCBs are contraindicated in patients with HFrEF, amlodipine, and felodipine are considered safe options in patients with HFrEF and concomitant SIHD or HTN.

CCBs undergo hepatic oxidative biotransformation via the cytochrome P450 isoenzyme 3A4 and other isoenzymes. Verapamil and diltiazem inhibit the clearance of other substrates for the 3A4 isoenzyme such as carbamazepine, cyclosporine, lovastatin, simvastatin, and benzodiazepines. The DHP CCBs do not produce a clinically meaningful interaction with these medications. Verapamil, and to a lesser extent diltiazem, also inhibit P-glycoprotein mediated drug transport. This interaction is partially responsible for increases in serum concentrations of agents such as digoxin and cyclosporine. Because verapamil decreases digoxin clearance, digoxin levels must be closely monitored if these agents are used together. Agents that induce the P450 3A4 isoenzyme can reduce the effectiveness of all CCBs. Potential pharmacodynamic interactions also need to be monitored in patients taking CCBs. Patients receiving verapamil or diltiazem concurrently with other agents that reduce HR and atrioventricular nodal conduction (β-blockers, digoxin, and amiodarone) should be monitored for the development of bradycardia or heart block.

Nitrates

7 Organic nitrates were found to have antianginal properties over 100 years ago when Murrell first reported in 1879, the ability of a 1% nitroglycerin solution administered orally to relieve and prevent angina attacks. Organic nitrates are prodrugs that require biotransformation into the active compounds. This process leads to denitration of the nitrate and the release of nitric oxide, also known as EDRF. Nitric oxide increases concentrations of cyclic guanosine monophosphate in the vascular endothelium leading to a reduction in cytoplasmic calcium and subsequent vasodilation. Vasodilation occurs predominantly in the venous vasculature thereby reducing preload, myocardial wall tension, and MVO_2. As doses are increased, arterial vasodilation also occurs. Arterial vasodilation can produce reflex tachycardia that can negate some of the antianginal benefits. Patients on adequate doses of β-blockers will not have reflex tachycardia, making this an effective combination for controlling a patient's acute and chronic angina symptoms.

Nitrates also vasodilate stenotic vessels as well as the intracoronary collaterals. Given that blood flow is exponentially related to the degree of stenosis, small increases in vasodilation in these narrowed vessels can produce significant increases in myocardial oxygen supply to ischemic areas of the myocardium. Nitrate-induced coronary vasodilation occurs predominately in epicardial vessels, with minimal effect on coronary microcirculation. This explains why nitrates do not cause coronary steal similar to other vasodilators like dipyridamole or sodium nitroprusside. In coronary steal, there is vasodilation in coronary vessels without atherosclerotic disease but coronary vessels with disease are not dilated. Therefore, more blood flow is shifted, or "stolen", to non-diseased vessels away from atherosclerotic vessels that have reduced blood flow. Nitrates may also have anti-aggregant effects on platelets, but the clinical impact is negligible.

Common adverse drug reactions from nitrate therapy include headache, flushing, nausea, postural hypotension, and syncope. While the hypotension is usually not severe, patients who are volume-depleted may experience paradoxical bradycardia if they attempt to rapidly stand. The headache will usually resolve after about 2 weeks when nitrates are used for chronic therapy. It is important to note that this does not represent tolerance or loss of antianginal effectiveness. Acetaminophen is effective in managing nitrate-induced headaches during the initial weeks of therapy. Patients using transdermal nitroglycerin may experience skin erythema and inflammation. Initiating therapy with smaller doses and rotating the application site can mitigate some of the adverse drug reactions of transdermal nitroglycerin

8 Several formulations of nitrates are available for acute and chronic use (Table 33-7). All patients with CAD should have access to SL nitroglycerin tablets or spray for the treatment of acute episodes of angina. Patient education is critical to ensure appropriate SL nitroglycerin use (Table 33-8). The SL route of administration avoids gastrointestinal absorption and hepatic first-pass metabolism. SL nitroglycerin 300 to 400 μg typically provides relief of angina within 5 minutes of administration. SL nitroglycerin can also relieve symptoms even if the patient is chronically taking long-acting nitrates. The adverse drug reactions of flushing, headache, and postural hypotension can appear rapidly and the patient should be aware of this potential. SL nitroglycerin can also be used to prevent acute episodes of angina. When patients want to participate in activities that they know lead to angina, they can take a dose of SL nitroglycerin 2 to 5 minutes in advance. This prophylactic dose provides up to 30 minutes of protection and allows patients to participate in activities that they might otherwise be unable.

TABLE 33-7

Nitrate Products

Product	Onset (minutes)	Duration	Initial Dose
Nitroglycerin			
IV	1-2	3-5 minutes	5-10 µg/min
Sublingual[*]	1-3	30-60 minutes	0.3-0.4 mg
Oral	40	3-6 hours	2.5-6.5 mg three times a day
Ointment	20-60	2-8 hours	0.5-1 in. (1.3-2.5 cm)
Patch	40-60	>8 hours	0.2-0.4 mg/hour (1 patch)
Isosorbide dinitrate			
Immediate release	20-40	4-6 hours	5-20 mg three times a day
Sustained release	60	8 hours	40 mg once daily
Isosorbide mononitrate			
Immediate release	30-60	6-8 hours	20 mg twice a day
Extended release	30-60	12-24 hours	30-60 mg daily

[*] Sublingual nitroglycerin exists in three different formulations: tablets, spray, and powder packets

TABLE 33-8

Appropriate Use of Sublingual Nitroglycerin

Education Point	Rationale
Keep in original dark glass container	SL nitroglycerin will interact with plastic and can lose potency when exposed to light. This is why it is packaged in a dark glass container.
Do not store in a larger plastic vial with a child-resistant safety cap	During an episode of angina, you do not want the patient struggling to figure out how to open the safety cap.
Do not store in the bathroom	SL nitroglycerin will degrade in moisture and tablets will lose their integrity and potency.
Keep SL nitroglycerin close by at all times; may need multiple vials	SL nitroglycerin does not do any good to the patient if they do not have it with them at the time of an episode of angina. The patient should consider having one at home, at work, in the garage, etc.
The patient should be sitting down and resting while taking the tablet	While the SL nitroglycerin tablets are small, the dose is not. It is likely the patient will have some flushing, may get a headache, and even become a little light-headed. They need to know this can happen.
Describe how to use a sublingual tablet	The SL nitroglycerin is administered under the tongue in order to provide rapid absorption and avoid first-pass metabolism. The patient needs to keep the tablet under the tongue until dissolved. Avoid swallowing the tablet.
Once opened, tablets need to be refilled every 6 months and spray every 3 years	Due to the instability of SL nitroglycerin tablets, they are typically only good for 6 months after the bottle is opened.[a] Shelf-life of the spray is longer. Patients need to be advised to refill SL nitroglycerin even if all doses have not been taken.
Remove the cotton plug from the bottle	Larger quantity bottles commonly have a cotton plug. During an episode of angina, you do not want the patient to be struggling with trying to get the cotton plug out of the bottle.
May be taken in advance of events known to cause chest pain	SL nitroglycerin can be used to prevent episodes of angina if taken before partaking in an exertional event known to precipitate angina/chest discomfort.
Contact 911 if first SL nitroglycerin does not relieve angina[b]	Most episodes of angina are relieved within 5-10 minutes of rest and a single SL nitroglycerin. If pain persists, the episode may be an acute coronary syndrome, not stable ischemic heart disease. This requires rapid medical attention.

[a] Product specific.

[b] May be patient-specific based on their experience with SL nitroglycerin and angina episodes.

The development of nitrate tolerance must be considered when chronically using long-acting nitrate therapy for SIHD. Several trials have shown that continuous nitrate therapy for more than 24 hours leads to a reduction or loss of the hemodynamic and antianginal effects of nitrates. In a large study in patients receiving 24 hours of transdermal nitroglycerin, almost all patients lost control of their angina symptoms within 24 hours to 1 week, which cannot be overcome with higher doses.[63]

Nitrate tolerance is not an “all or none” phenomenon. Responsiveness is reduced in some patients while others experience a total loss of efficacy. Despite the continued use of nitrates and a loss of antianginal effect, plasma volume remains expanded and some hemodynamic effects are maintained. Chronic administration of nitrates produces a state of oxidative stress leading to dysfunction of mitochondrial aldehyde dehydrogenase, the enzyme responsible for converting nitrates to the active agent NO.[64,65] Consequentially, the dysfunctional enzyme is unable to produce active NO and the angina relieving effect of nitrate agents is reduced or lost.

Why nitrate tolerance develops remains unknown, but several pharmacologic approaches have been developed to manage and prevent it. One thought is that tolerance is due to an exhausting of sulfhydryl groups needed to use organic nitrates.[64] Based on this hypothesis, acetylcysteine and ACE inhibitors such as captopril, which supply sulfhydryl groups, have been investigated as a potential strategy for preventing nitrate tolerance. Unfortunately, both agents have provided inconsistent results. ACE inhibitors may prevent nitrate tolerance through other mechanisms. The inhibition of angiotensin II production can reduce superoxide anion production, leading to reduced nitrate degradation, as well as a reduction in protein kinase C and endothelin leading to a reduction in vasoconstriction. Unfortunately, none of these approaches have shown to be effective in maintaining the antianginal effects of continuous nitrate therapy.

The preferred management of nitrate tolerance for patients with CAD is to ensure a 10- to 14-hour nitrate-free interval every day. This approach has been shown to maintain antianginal efficacy with the use of chronic nitrates. The rationale for this approach is based on the observation that although nitrate tolerance develops rapidly, it is also reversed rapidly. Unfortunately, this approach does not provide the patient with anti-ischemic coverage for a full 24 hours and places the patient at risk for angina episodes. Typically, the nitrate-free interval is provided during the nighttime hours when the patient is sleeping and, in most cases, has lower MVO_2. Several trials have used chronic nitrates with a daily nitrate-free interval and demonstrated increased exercise time, reduced exercise-induced ischemic events, and reduced need for SL nitroglycerin. Despite these benefits, a nitrate-free interval would not provide protection to the 20% to 30% of patients with SIHD who experience nocturnal episodes of angina. Moreover, it is well documented that angina episodes and MI commonly occur in the morning hours, immediately before or after awakening. Patients using chronic nitrate therapy are unlikely to have taken or applied their nitrate therapy for the day during this critical time period. Therefore, nitrates should not be routinely used as monotherapy in patients with SIHD due to the lack of 24-hour coverage, lack of protection against circadian-related ischemic events, and potential for reflex tachycardia. Trials have demonstrated that patients taking intermittent transdermal nitroglycerin did not experience rebound ischemia during the nitrate-free interval when β-blockers or diltiazem were concurrently used.

⑦ Several nitrate preparations can be used for chronic long-term prevention of angina episodes. Transdermal patches and isosorbide mononitrate are the most commonly prescribed chronic nitrates. Although isosorbide dinitrate is effective, the three times daily dosing regimen requires patients to take a dose every 4 to 5 hours in order to provide an adequate nitrate-free interval. Two of the isosorbide mononitrate preparations are dosed twice daily. The twice-daily preparations should be dosed 7 hours apart, such as 7 am and 2 pm. It is critical to be specific about the times each dose should be taken so that patients do not take the doses 12 hours apart, thus compromising the nitrate-free interval. One isosorbide mononitrate preparation is dosed once daily. It is an extended-release preparation that provides 12 hours of nitrate exposure. This should be followed by a 12-hour nitrate-free interval. Transdermal nitroglycerin patches are typically prescribed as “on in the am and off in the pm.” It is best to provide specific times for application and remove (eg, apply at 8 am and remove at 8 pm). Patients who work evening or night shifts need to have the timing of their nitrate doses adjusted to coincide with when they are active during the day.

Ranolazine

Unlike other agents used for angina, ranolazine does not impact HR, BP, the inotropic state, or coronary blood flow. Animal studies have demonstrated that ranolazine has little affinity for α_1, β_1, and β_2 adrenoreceptors and has minimal calcium channel blocking activity. Ranolazine reduces ischemic episodes by selective inhibition of late sodium current (I_{Na}). Total sodium entry during an action potential is comprised of an early (fast) and late (slow) component. Under normal conditions, late I_{Na} constitutes only 1% of total I_{Na}. Several preclinical studies have observed an increase in late I_{Na} in ischemic and failing hearts.[66] It is not fully appreciated if this increase in late I_{Na} is due to an increase in the density of the late Na^+ channels or dysfunction of these channels. The increase in intracellular Na^+ triggers an increase in the influx of Ca^{2+} through the reverse mode of the Na^+/Ca^{2+} exchanger, resulting in intracellular Ca^{2+} overload and eventually myocardial stunning.[66] Therefore, it is not the intracellular Na^+ concentration that produces ischemic damage, but its recognized role in Ca^{2+} accumulation via Na^+/Ca^{2+} exchange.[66] By inhibiting late I_{Na}, ranolazine produces a reduction in intracellular Na^+. The reduction in intracellular Na^+ contributes to a reduction in the magnitude of ischemia-induced Ca^{2+} overload and improves myocardial function as well as myocardial perfusion.[66]

Ranolazine is available as a sustained-release preparation dosed twice daily. With a half-life of approximately 7 hours, ranolazine achieves a steady-state within 3 days. Since ranolazine 1000 mg twice daily significantly improves exercise tolerance more than 500 mg twice daily, titration to 1000 mg twice daily should be attempted. When ranolazine was added to atenolol (50 mg daily), diltiazem (180 mg daily), or amlodipine (5 mg or 10 mg daily), there was an increase in exercise duration, time to angina, time to 1 mm ST-depression, and a reduction in the number of angina episodes and SL nitroglycerin tablets used per week compared to placebo.[67,68] In these trials, the magnitude of increase in exercise duration during testing was associated with a 25% reduction in the weekly number of angina episodes and SL nitroglycerin use over placebo and almost a 50% reduction from baseline.[68,69] The improvement in exercise duration demonstrated with ranolazine is consistent with results produced with β-blockers, CCBs, and chronic nitrates.[8,70]

Patients should be initiated on ranolazine 500 mg twice daily, with the dose increased to 1000 mg twice daily within the next 1 to 2 weeks if tolerated. Ranolazine is primarily metabolized by CYP3A4 (70%-85%) and CYP2D6 (10%-15%) in the liver and is a substrate for *P*-glycoprotein, making it prone to several clinically important drug interactions. Potent inhibitors of CYP3A4 and *P*-glycoprotein such as ketoconazole, itraconazole, protease inhibitors, and clarithromycin will significantly increase ranolazine drug concentrations. Conversely, potent CYP3A4 inducers such as phenytoin, phenobarbital, carbamazepine, rifampin, rifabutin, rifapentine, and St. John's wort significantly decrease ranolazine drug concentrations. Concurrent use of these strong inhibitors and inducers with ranolazine is contraindicated. Moderate inhibitors of CYP3A4 such as diltiazem, verapamil, erythromycin, and fluconazole, can be used with ranolazine, but the dose should not exceed 500 mg twice daily. Due to inhibition of CYP3A4 by ranolazine, doses of simvastatin should not exceed 20 mg daily. Ranolazine increases digoxin 1.4- to 1.6-fold at trough and 2-fold at peak plasma concentrations, likely through competition for intestinal and renal *P*-glycoprotein. Digoxin doses may need to be reduced to avoid toxicity. Agents that are potent inhibitors of *P*-glycoprotein, such as cyclosporine, may increase ranolazine concentrations and adverse drug reactions. The dose of ranolazine should be reduced.

Ranolazine and metformin compete for renal clearance through the organic cation transporter 2, which has the potential to increase metformin drug concentrations and increase the risk of lactic acidosis. This interaction is only clinically meaningful when both full-dose ranolazine (1,000 mg twice daily) and full-dose metformin (1,000 mg twice daily) are used together. In this setting, the metformin dose should be reduced to 850 mg twice daily. Patients on ranolazine 500 mg twice daily do not need to alter their metformin doses. Ranolazine produces reductions in A1c by 0.6% to 0.7% (0.006-0.007; 7-8 mmol/mol).[68,71] Reductions in blood glucose were observed in patients with or without diabetes, without causing hypoglycemia. While ranolazine is not a treatment for DM, clinicians may find this property useful.

The most common adverse drug reactions from ranolazine use are constipation, nausea, dizziness, and headache. At therapeutic doses, ranolazine produces a modest prolongation of QTc (15 msec or less). A linear relationship exists between ranolazine plasma concentration and the QTc interval, but the effect is modest when used at recommended doses. Patients should not receive doses of more than 1,000 mg twice daily and caution should be used in patients receiving concomitant QTc-prolonging agents.

While ranolazine is safe and effective for treating angina episodes, it would only be an option as monotherapy in patients with SIHD who cannot tolerate traditional antianginal agents due to hemodynamic or other adverse drug reactions. Ranolazine is recommended as an add-on therapy to traditional antianginal agents. In patients who have achieved HR and BP targets on maximally tolerated doses of traditional agents but continue to have exertional angina symptoms, ranolazine is a reasonable choice because it does not impact these hemodynamic parameters.

Nonpharmacologic Therapy (Revascularization)

Surgical revascularization plays arole in the treatment of SIHD. The most common revascularization procedures are coronary artery bypass grafting (CABG) surgery or PCI with or without stent placement. In 2017, more than 600,000 PCI procedures were performed in the United States and approximately a third of these were done electively (e.g. in patients with SIHD).[72] Stents are placed in over 90% of patients undergoing PCI, with drug-eluting stents (DES) accounting for 82% of all stents. Bare metal stent (BMS) are placed less commonly (18%). Approximately 371,000 CABG surgeries are performed annually.[2] Other revascularization options are under development.

⑨ The primary goal of revascularization is to prolong life and, secondarily, to eliminate or reduce symptoms. Revascularization is recommended over medical therapy as initial management of SIHD in select patients, such as those with with significant stenosis of the left main coronary artery, multivessel disease and LV dysfunction, or refractory angina. Whereas most of the pharmacologic approaches reduce MVO_2, revascularization increases myocardial oxygen supply in vessels with critical stenosis. This is accomplished by opening the vessel (PCI) or using alternative transplanted vessels to bypass a critical stenosis (CABG). While both procedures are highly effective and have advantages in certain groups of patients over pharmacologic approaches, both have limitations.

Percutaneous Coronary Intervention

The term PCI encompasses the use of balloon angioplasty with stent placement as well as other less commonly performed intracoronary procedures such as rotational atherectomy and aspiration thrombectomy. During a PCI, a catheter is guided into coronary arteries through either femoral or radial access. A sheath is placed in either the femoral or radial artery to maintain access during the procedure. A guide catheter is then introduced through the sheath and advanced to the ostium of the coronary arteries. A guidewire is then advanced through the guide catheter and across the stenosis in the coronary vessel. The deflated balloon is then slid along the guidewire and to the site of the coronary stenosis. The balloon is then inflated. The inflated balloon expands the coronary lumen by stretching and tearing the atherosclerotic plaque (see Acute Coronary Syndromes, Chapter 34 for detailed review). Most elective PCI procedures are completed in 30 to 60 minutes.

Abrupt vessel closure is a potential complication of balloon angioplasty. Abrupt vessel closure is provoked by physical disruption of the plaque on the vessel walls during the procedure. In the past, this complication occurred in 5% to 8% of cases and required emergency CABG surgery in 3% to 5% of patients. A second complication from PCI is restenosis, which can lead to recurrent symptoms and the need for another revascularization procedure in approximately 30% to 50% of patients within a year.[73] These complications have now been dramatically reduced with the use of antithrombotic therapy and intracoronary stents.

Stents are scaffolds made from stainless steel or other metal alloys placed within coronary arteries that can prevent acute vessel closure and restenosis. The stent is placed over the deflated balloon and advanced to the area of coronary stenosis. When the balloon is inflated, the stent expands into the coronary vascular wall. The balloon is then deflated, leaving the expanded stent permanently in the diseased coronary vessel. While stents have had a dramatic effect of reducing restenosis, and therefore repeat revascularization procedures, they do not prevent death or MI more effectively than balloon angioplasty alone.

Restenosis is a phenomenon characterized by a greater than 50% diameter loss in the vessel lumen at the site of the intervention. Restenosis most often occurs within the first 3 to 6 months following the procedure. The pathophysiology of restenosis involves a complex cascade of various growth factors and cytokines that promote smooth muscle cell proliferation and result in a progressive loss of luminal diameter.[73] Restenosis typically occurs through the following mechanisms: early vessel recoil, late constrictive remodeling, and neointimal proliferation.[73]

Elastic recoil is a nearly instantaneous phenomenon, occurring during the first hour after the successful dilation of the vessel. As the vessel is stretched during balloon angioplasty, the endothelium lining the vessel becomes damaged. In response to the stretching, the fibers begin to recoil back to their previous size.[73] Late constrictive remodeling, also referred to as negative remodeling, is mediated by myofibroblasts of the adventitia layer of the coronary vessel. Balloon-induced injury often results in exposure of the adventitia to the lumen. Cell proliferation begins as activated fibroblasts contribute to the enlargement of the adventitia. These activated fibroblasts differentiate into myofibroblasts that are involved in the profibrotic and remodeling effects of the vessel.[73] As the adventitia becomes thick and fibrotic, a decrease in arterial cross-sectional area results.

The scaffold-like properties of a BMS prevent restenosis by controlling elastic recoil and negative remodeling. Restenosis rates dropped from 30% to 50% with balloon angioplasty alone to 15% to 30% with the use of BMS. However, stent-induced vessel injury and inflammatory reactions around the stent struts trigger a set of events that promote neointimal hyperplasia, a normal response to vascular damage.[73] The anti-proliferative drugs used in DES target neointimal hyperplasia. DES are coated with sirolimus, paclitaxel, zotarolimus, or everolimus. These agents interrupt the cell cycle to prevent neointimal proliferation and reduce restenosis rates to 5% to 10%.[73]

Although stents can effectively reduce restenosis, the exposed stent struts can provoke thrombosis. Stent thrombosis is driven by the implantation of the stent into an atherosclerotic plaque, exposing platelet adhering proteins to the stent surface. Patients remain at risk for stent thrombosis until a thin layer of endothelial tissue can grow around the stent struts. This process is called re-endothelialization and typically occurs in 2 to 4 weeks after BMS deployment, with most adverse events occurring within the first 2 weeks. The process of re-endothelialization is significantly prolonged with the use of DES. The drugs in a DES prevent smooth muscle, neointimal, and endothelial cell growth. Therefore, while DES effectively reduces neointimal proliferation and the risk of restenosis, they also increase the period of risk for stent thrombosis.

Stent thrombosis is uncommon (<5% of cases) but catastrophic when it occurs. Stent thrombosis results in a large MI or death in two-thirds of cases. The mortality rate from stent thrombosis ranges from 20% to 45%. Stent thrombosis can be largely prevented by using DAPT.

Pharmacotherapy with PCI

The physical damage imposed on the atherosclerotic plaque during PCI with stent placement induces platelet recruitment and activation, leading to the potential for thrombus formation. Therefore, antithrombotic therapy with antiplatelet and anticoagulant agents are necessary to produce a successful outcome. Antiplatelet therapy is also used after the procedure to reduce the risk of stent thrombosis.

All patients without a contraindication should receive aspirin before PCI. Patients already on chronic aspirin therapy should take an additional 75 to 325 mg before PCI. Aspirin-naïve patients should be given a dose of 325 mg, preferably at least 2 but up to 24 hours before PCI. Chronic treatment with aspirin 81 mg daily is recommended after PCI. Patients receiving a stent should also receive a $P2Y_{12}$ inhibitor (eg, clopidogrel) before PCI. The ACC/AHA guidelines recommend against stent placement if it is believed the patient will not tolerate or comply with the recommended duration of DAPT.[1]

After elective PCI, DAPT should be continued to reduce the risk of stent thrombosis. For patients who receive a BMS, a minimum of one month of DAPT is sufficient.[74] In patients at high risk of bleeding, a minimum of 2 weeks can be given, as most re-endothelialization of the stent surface occurs within 2 weeks. Patients receiving a DES should receive at least 6 months of DAPT due to the delayed and somewhat unknown duration of the re-endothelialization process.[73,74] However, it is reasonable for those patients who receive a DES and are at high risk of bleeding or develop significant bleeding to stop the $P2Y_{12}$ inhibitor after only 3 months of therapy[74] An alternative approach in patients undergoing PCI for SIHD, continuing the P2Y12 inhibitor but discontinuing aspirin 1-3 months after PCI, reduces the risk of bleeding and may be considered.[75]

The results of the DAPT (Dual Antiplatelet Therapy Trial) found that a longer duration of DAPT (up to 30 months) provides a greater reduction in CV adverse events when compared to 12 months of treatment, but also a significant increase in major bleeding.[76] Therefore, the guidelines state that a longer treatment regimen for both BMS and DES can be considered in patients who have tolerated therapy, are not at high risk of bleeding, nor have experienced any bleeding complications. This longer duration of DAPT for patients receiving a DES is a Class IIb recommendation.[74]

PCI Versus Medical Management

Despite advancements in PCI technique and stent technology, no study to date has demonstrated that PCI in patients with SIHD improves survival. This is most likely due to the advancements in pharmacotherapy and the use of GDMT. PCI resulted in fewer angina episodes when compared to medical therapy, but in these trials PCI rarely included the use of stents and medical therapy did not include the use of high-intensity statins or ACE inhibitors.[77]

Contemporary PCI and GDMT have been compared in recent clinical trials. In the COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) trial, the rate of death and MI were not different between patients who were randomized to GDMT alone compared to PCI with GDMT (19.0% in PCI group vs 18.5% in GDMT group).[78] While more patients were angina-free in the PCI group compared to the GDMT group at one year (66% vs 58%), there was no difference at the 5-year follow-up time point (74% vs 72%). The need for revascularization after 5 years was lower in the PCI group (21.1% vs 32.6%). This trial confirms that PCI with GDMT does not lower the risk of death and MI compared to GDMT alone, and PCI should be reserved for patients with SIHD refractory angina after receiving optimal GDMT. These data underscore the importance of aggressive, goal-oriented, pharmacotherapy in patients with SIHD. While one-third of patients in the COURAGE study randomized to the GDMT group did need to receive PCI during the 5-year study, two-thirds did not. Similar to the COURAGE trial, the incidence of CV death, MI, and CV hospitalizations (unstable angina, HF, or resuscitated cardiac arrest) was not significantly different between patients with SIHD treated with an initial invasive strategy consisting of coronary angiography, revascularization, and GDMT compared to an initial conservative strategy in, the more recent ISCHEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) trial.[79]

Thus, based on the available evidence, PCI cannot be supported as the initial management strategy in most patients with SIHD. Existing evidence suggests that PCI in SIHD should be reserved for patients with chest pain despite optimal GDMT often referred to as refractory angina.

Coronary Artery Bypass Graft Surgery

⑨ While PCI is the most common form of revascularization, CABG surgery is recommended to prolong survival or relieve refractory symptoms of angina in select patients.[1,80,84] In the majority of CABG surgeries, a sternotomy, and division of the sternum is done to provide the surgeons with direct access to the heart. Thus, it is often referred to as “open-heart surgery”. Once the heart is exposed, vascular conduits surgically harvested from other areas of the body are used to "bypass" the atherosclerotic plaque. The most commonly used vascular conduits are the saphenous vein grafts (SVG) from the leg and the left internal mammary artery (LIMA) from the chest wall. The radial and gastroepiploic arteries are also occasionally used. When a LIMA graft is performed, the distal portion is detached from its insertion point behind the sternum and an anastomosis is made distal to the atherosclerotic plaque of the diseased coronary artery to restore blood flow beyond the blockage. The other vascular conduits (eg, SVG) are considered "free grafts" and are anastomosed distally to atherosclerotic plaques of the other diseased coronary arteries. The proximal ends of the free grafts are then anastomosed to the aorta restoring blood flow distal to the blockage. Prior to and during the anastomoses of the bypass grafts, patients are often placed on cardiopulmonary bypass which redirects blood from the heart to a bypass machine. In the bypass machine, venous blood is oxygenated and then returned to the systemic circulation to maintain myocardial and systemic perfusion during the surgery. The heart is then arrested allowing the surgeon to perform the surgery without the heart actively beating. After the bypass grafts have been installed, the patient is weaned from the cardiopulmonary bypass machine, the heart and lung resume their normal functioning, the cannulas are removed, and the sternum and incisions are closed.

While a critical obstruction of a native coronary vessel due to atherosclerosis usually takes five or more decades, the lifespan of an SVG is significantly shorter. This is due to the higher BP in arterial circulation compared to venous pressures. Endothelial damage and LDL-C accumulation significantly accelerate the atherosclerotic process. The use of arterial grafts provides greater long-term graft patency compared to SVG. Arterial grafts are more prone to vasospasm and require longer surgical times to harvest.

Despite the advancements in technique and patient care, CABG surgery is associated with several complications. Death, neurological impairment, MI, major bleeding, acute kidney injury, atrial fibrillation, and surgical wound infections are all potential complications following CABG surgery. Early mortality within 30 days is generally low (1%-2%) but is higher in emergent or high-risk cases (eg, multiple comorbidities, older patients).[82] Neurological complications such as stroke (1%-3%), delirium (8%-50%), and cognitive deficits can occur due to hypoxia, emboli, hemorrhage, or a metabolic abnormality during or shortly after the surgery.[82] Patients with advanced age, previous stroke or transient ischemic attack, HTN, ASCVD, atrial fibrillation, and prolonged cardiopulmonary bypass duration are at higher risk of neurological complications. Atrial fibrillation occurs in as many as 30% of patients undergoing CABG surgery but is often transient. An infection of the sternum, known as mediastinitis, occurs in 0.5%-3% of patients and may prolong hospital stays, increase recovery time, and result in repeat surgical intervention.[82] MI, major bleeding requiring surgical re-exploration, and acute kidney injury requiring hemodialysis each occur in 1% to 4% of patients following CABG surgery.[82]

New approaches to CABG surgery have been developed in an attempt to minimize complications. One of these approaches is the off-pump bypass coronary surgery that is performed while the heart is beating. By reducing the need for cardiopulmonary bypass and aortic clamping, rates of adverse neurologic and renal events are significantly lower.[82] Another approach to surgical revascularization is the use of minimally invasive direct coronary artery bypass during which a small left anterior thoracotomy is done in lieu of a sternotomy. Due to the small incision and technical difficulty of the surgery, only patients with single-vessel disease in either the left anterior descending or right coronary artery currently are candidates for the procedure. Although postoperative pain is often increased, clinical outcomes of minimally invasive direct coronary artery bypass are similar to conventional CABG but recovery time is quicker.[82]

In suitable surgical candidates, CABG surgery is the preferred revascularization strategy in several clinical scenarios. Examples include patients with left main CAD (≥50% stenosis) "unprotected" by collateral coronary blood flow or patent bypass grafts, 2-vessel CAD (≥70% stenosis in the proximal left anterior descending coronary artery and one additional major coronary artery), and multivessel CAD (≥ 70% stenosis in three or more major coronary arteries). CABG surgery is preferred to PCI and medical management because it is associated with prolonged survival.[84] CABG surgery is also recommended to decrease mortality in patients who survived an episode of sudden cardiac death due to ischemia from significant (≥70% stenosis) CAD in one or more arteries. In patients with SIHD whose symptoms are refractory to GDMT, CABG surgery may be considered.[1,84] However, because it is less invasive than CABG surgery, PCI is often the preferred strategy in this setting.

Pharmacotherapy with CABG

Prior to CABG surgery, attention to pharmacotherapeutic needs is important to minimize postoperative complications. Patients taking aspirin 81 to 325 mg daily preoperatively should continue taking aspirin until the time of surgery to reduce ischemic events. Although patients undergoing elective CABG who were not taking aspirin preoperatively have commonly been initiated on aspirin within 24 hours of surgery, this approach offers no benefit and is no longer recommended.[84] To reduce the risk of CABG-related major bleeding, $P2Y_{12}$ inhibitors should be discontinued well in advance of an elective

CABG surgery (5 days for clopidogrel and ticagrelor; 7 days for prasugrel) and at least 24 hours prior to urgent CABG surgery, if possible. Initiation of β-blockers or amiodarone prior to CABG surgery may be considered to reduce the risk of postoperative atrial fibrillation.[84]

Pharmacotherapy after CABG surgery includes aspirin, high-intensity statins, β-blockers, and the continuation of ACE inhibitors (ACC/AHA Class I recommendations).[1,84] Aspirin 81 to 325 mg daily should be resumed or initiated within 6 hours of CABG surgery and continued indefinitely to reduce the risk of graft closure and acute MI. If patients are truly aspirin allergic, clopidogrel is an acceptable alternative. For patients treated with DAPT following PCI who subsequently undergo CABG surgery, DAPT should be resumed postoperatively and continued for the initially recommended duration of therapy is completed.[74] Due to the accelerated atherosclerotic process in the bypass grafts, high-intensity statin therapy should be resumed or initiated in all patients following CABG surgery. β-blockers should be initiated after CABG surgery to reduce the incidence of postoperative atrial fibrillation.[84] The safety and efficacy of initiating ACE inhibitors following CABG surgery are uncertain and may increase the risk of hypotension and acute kidney injury, particularly if administered during the early postoperative period.[81] However, the continuation of previous ACE inhibitor therapy following CABG surgery is associated with a significant reduction in nonfatal cardiac, cerebral, and renal events whereas ACE inhibitor withdrawal following CABG surgery is associated with increased event rates.[83] Therefore, for patients taking ACE inhibitors or ARBs prior to CABG surgery, these therapies should be resumed following surgery once patients have demonstrated stable hemodynamics and renal function.[81] For ACE inhibitor-naïve patients, initiation of an ACE inhibitor should be considered in stable patients with compelling indications (eg, HFrEF, HTN, DM, and chronic kidney disease).[81] For symptomatic relief of chest pain episodes, patients need access to SL nitroglycerin after surgery. Smoking cessation and cardiac rehabilitation are also critical to successful postoperative outcomes.

Management of Angina

⑧ Medical management of angina episodes follows a stepwise approach (see Fig. 33-2 and Table 33-6). All patients should have access to SL nitroglycerin for the treatment of an acute episode of angina. Patients need to be adequately educated on appropriate use and storage, assuring consistent access to the tablets or spray (Table 33-8). This may require patients to have multiple vials or canisters that are in areas that they spend time (eg, home, work, car). While some patients may only need SL nitroglycerin for infrequent attacks, many patients with SIHD will need chronic therapy to prevent angina episodes. Patients experiencing frequent angina episodes or in whom angina is impacting the quality of life should receive chronic therapy. The goal of chronic therapy is to provide complete or nearly complete elimination of angina episodes while having the patient take part in normal activities.

Since increased heart rate can increase MVO_2 and precipitate angina, either a β-blocker or a non-DHP CCB (verapamil or diltiazem) can be used for the initial chronic management of angina. The goal is to lower the patient's resting HR to 50 to 60 beats per minute and an exercise HR of less than 100 beats per minute. Not all patients, especially older adults, can tolerate an HR in this range; the goal HR would be as low as the patient can tolerate above 50 beats per minute. Both β-Blockers andCCBs can improve exercise duration and reduce the number of weekly angina episodes.[70]

⑥ β-Blockers are recommended over CCBs as initial therapy for control of angina episodes in patients with SIHD.[1] This recommendation is based on improved survival demonstrated with the use of β-blockers in patients after MI and with HFrEF. Only carvedilol, metoprolol succinate, and bisoprolol should be used in patients with HFrEF, starting with low doses and titrating up in a slow and set regimen. CCBs have not demonstrated similar benefits in patients following an MI or with HFrEF. Patients with contraindications or intolerable adverse drug reactions to β-blocker therapy may be treated with a CCB, with verapamil or diltiazem preferred. In patients without a history of MI or HF, the use of β-blocker therapy does not provide a survival advantage and is used purely for the control of ischemic episodes and symptoms of angina.[70]

⑤ If angina symptoms are controlled once the HR goal is achieved, no additional antianginal therapy is necessary and patients are monitored for continued efficacy and adverse drug reactions. Regardless of whether a β-blocker or CCB are selected as initial therapy, many patients will require combination therapy to attain adequate control of their symptoms. If additional therapy is required, the need for additional antihypertensive agents should be considered in the next step. Patients with angina symptoms refractory to β -blockers who continue to have elevated BP above the goal of 130/80 mm Hg should be prescribed a DHP CCB. Unlike long-acting nitrates and ranolazine, DHP CCBs decrease both MVO_2 and BP. While not commonly combined, DHP CCB and non-DHP CCB target different calcium channels and are a rational regimen for patients with SIHD with contraindications or intolerance to β -blockers.. It is important to monitor the patient for peripheral edema and signs and symptoms of reduced cardiac output.

7 In patients with continued angina episodes despite achieving BP and HR goals, a long-acting nitrate or ranolazine should be added to the regimen. Both agents have demonstrated efficacy when used in combination with SL nitroglycerin and medications to control HR and BP. While long-acting nitrates are not optimal agents when used as monotherapy due to reflex tachycardia, this is attenuated in patients who are taking a β-blocker or non-DHP CCB. Ranolazine does not reduce HR or BP, making it an option in patients who have already achieved their HR and BP goals, but still have exertional angina. The selection of a long-acting nitrate or ranolazine should be based on patient preferences, tolerability, and cost. Long-acting nitrates do not provide 24-hour angina protection, but this may not be an issue for all patients. While ranolazine provides 24 hours protection and has a more attractive adverse drug reaction profile compared to long-acting nitrates, it is more expensive.

Patients who are unable to fully participate in the activities that bring them joy in life because of inadequate control of chest pain symptoms, despite the use of maximally tolerated therapies, have refractory angina. Some patients may have refractory angina while taking relatively fewer antianginal medications or lower doses due to intolerances or contraindications. Patients with refractory angina should be referred for revascularization therapy.

Management of Prinzmetal's Angina

Patients with variable-threshold angina require pharmacotherapy that targets vasospasm. While β-blockers are typically the agents of first choice in patients with fixed-threshold angina, they are less useful in patients with vasospasm. Although not all studies report increased chest pain episodes with β-blockers in patients with vasospasm, they can induce coronary vasoconstriction and prolong ischemia. Worsening angina is most likely due to unopposed α1-adrenergic receptor stimulation during β-blockade. A similar phenomenon may occur in patients with SIHD treated with β-blockers who also abuse cocaine or methamphetamines.

Both nitrates and CCBs reduce vasospasm. Most patients respond well to SL nitroglycerin for acute attacks. While long-acting nitrates can be used in the treatment of vasospasm, the high doses typically needed for adequate symptom control are not well tolerated. Therefore, CCBs are often used. There is no preference to which agent is selected first, but CCBs are dosed less frequently and a single agent may be sufficient to manage symptoms. Nifedipine, verapamil, and diltiazem are all equally effective for the initial management of coronary vasospasm. Dose titration is important to maximize the response with CCBs. Patients unresponsive to calcium antagonists alone may add long-acting nitrates.

EVALUATION OF THERAPEUTIC OUTCOMES

The therapeutic goals in the management of patients with SIHD are to prolong life, reduce symptoms of angina, and improve quality of life. Improving the patient's quality of life requires careful attention to the potential adverse drug reactions from medications. Surrogate endpoints such as BP goal attainment, use of high-intensity statin, A1c goal attainment, smoking cessation, and achieving a healthy weight should be used to determine progress toward the ultimate goal — reduced risk of mortality and major cardiovascular events. Patients should be evaluated every 1 to 2 months until goals are achieved. Follow-up every 6 to 12 months thereafter is appropriate.

3 Monitoring for improvements in symptoms related to angina should include asking the patients about the number and severity of angina episodes and weekly SL nitroglycerin use as well as inquiring about exercise capacity or duration of exertion needed to induce angina. It is important to ask the patient about their ability to engage in activities they want to do. It is not uncommon for patients to report reduced or no episodes of angina because they have stopped engaging in activities that bring on angina. Patients experiencing worsening angina may complain of increasing frequency and severity of symptoms, increased SL nitroglycerin use, decreased exercise capacity, or a combination of these. Once patients have received optimal medical therapy, symptoms should improve in 2 to 4 weeks and remain stable until the disease progresses. Instruments such as the Seattle Angina Questionnaire and CCS Angina Grading Scale can be used to improve the assessment of symptoms.[1] While objective tests such as an exercise tolerance test with or without cardiac imaging can be obtained to assess the adequacy of treatment, they are primarily performed in patients who do not achieve adequate symptom control. Following a revascularization procedure, the patients' symptoms should be assessed every 6 to 12 months.

ABBREVIATIONS

ACC	American College of Cardiology

SELF-ASSESSMENT QUESTIONS

1. A 56-year-old patient had coronary artery bypass graft (CABG) surgery performed for refractory symptoms of angina despite maximally tolerated medical therapy and multiple percutaneous coronary interventions. Which of the following medications should be initiated following CABG surgery and continued indefinitely to maintain patency of the saphenous vein grafts?

   A. Aspirin

   B. Rivaroxaban

   C. Ticagrelor

   D. Warfarin

2. Which of the following best explains why ischemia does not typically occur with exertion in patients with stable ischemic heart disease until coronary stenosis reaches 70% or more of the luminal diameter?

A. Atherosclerotic plaque rupture beyond this degree of coronary stenosis

B. Collateral circulation diminishes as coronary stenosis increases

C. Coronary flow reserve is exhausted as the degree of coronary stenosis increases

D. Vasospasm occurs once coronary stenosis exceeds 70% of luminal diameter

3. Which of the following patients with stable ischemic heart disease is more likely to experience atypical symptoms of angina? (Key Concept #2)

A. 46-year-old with hypertension, dyslipidemia, and obesity

B. 54-year-old with gastroesophageal reflux disease and dyslipidemia

C. 62-year-old with atrial fibrillation, stroke, and chronic kidney disease

D. 76-year-old with hypertension, dyslipidemia, and diabetes

4. A patient with stable ischemic heart disease is being evaluated for control of angina symptoms. The patient reports experiencing angina symptoms one to two times weekly, unchanged from baseline. Angina symptoms are typically provoked when walking up stairs, consistent with baseline. The chest discomfort is described as 5 out of 10, similar to baseline. The patient reports using 3 to 4 tablets/week of sublingual nitroglycerin compared to 1 to 2 tablets/week at baseline. His blood pressure is 132/84 mm Hg, heart rate is 70 beats per minute. Which of the following suggest worsening angina control?

A. Frequency of angina symptoms

B. Provoking factors

C. The severity of angina symptoms

D. Sublingual nitroglycerin use

5. A 63-year-old female with hypertension, diabetes, dyslipidemia, and obesity is newly diagnosed with stable ischemic heart disease. Blood pressure is 148/86 mm Hg, heart rate is 64 beats per minute. Weight is 104 kg; body mass index is 43.3 kg/m^2. LDL cholesterol is 127 mg/dL (3.28 mmol/L) and hemoglobin A1c is 8.3% (0.083; 67 mmol/mol). Which of the following risk factor modification goals is appropriate for this patient?

A. Blood pressure <130/80 mm Hg

B. Body mass index <30 kg/m^2

C. Hemoglobin A1c <6.5% (0.065; 48 mmol/mol)

D. LDL cholesterol <70 mg/dL (1.81 mmol/L)

The next two questions (#6 and #7) refer to the following case.

A 68-year-old male presents with complaints of angina when walking two flights of stairs. The pain is relieved with rest and only occasionally requires a dose of SL nitroglycerin for relief. His PMH includes a history of MI 3 years ago, HTN, and hyperlipidemia. He quit smoking 3 years ago after his MI. His home medications include aspirin 81 mg daily, metoprolol 25 mg twice daily, and atorvastatin 80 mg daily. Vital signs: BP is 158/92 mm Hg, HR 82 bpm.

6. Which of the following is most appropriate to treat this patient's angina?

A. Add lisinopril 10 mg daily

B. Add ranolazine 1,000 mg twice daily

C. Add SL nitroglycerin 1 tablet as needed for angina

D. Increase metoprolol to 50 mg twice daily

7. The patient returns for a cardiology appointment 6 weeks later and states that his angina has improved and he is feeling much better. His laboratory findings are within normal limits. Vital signs: BP is 140/88 mm Hg, HR 68 bpm. LDL 67 mg/dL (1.73 mmol/L). Which of the following is most appropriate to consider in this patient to reduce mortality?

   A. Clopidogrel 75 mg daily

   B. Lisinopril 5 mg daily

   C. Ezetimibe 10 mg daily

   D. Hydrochlorothiazide 25 mg daily

8. A 74-year-old female undergoes PCI for stable angina symptoms and receives a drug-eluting stent in her right coronary artery. Which of the following is recommended post-PCI?

   A. Aspirin 325 mg daily plus clopidogrel 75 mg daily for 6 months

   B. Aspirin 81 mg daily plus ticagrelor 90 mg twice daily for 1 month

   C. Aspirin 325 mg daily plus ticagrelor 90 mg twice daily for 1 month

   D. Aspirin 81 mg daily plus clopidogrel 75 mg daily for 6 months

9. A patient presents to his local pharmacy with a new prescription for SL nitroglycerin tablets. Which is not correct patient counseling information to give the patient?

   A. This medication is only for the treatment of acute anginal attacks.

   B. Keep the bottle in the original glass bottle as the medication is sensitive to light.

   C. Be sure to sit down before taking this medication as it may cause dizziness.

   D. It is recommended to replace the bottle every 6 months to ensure optimal potency.

10. A 75-year-old patient with SIHD presents with continued angina. His home medications include aspirin 81 mg daily, allopurinol 100 mg daily, lisinopril 20 mg daily, carvedilol 25 mg twice daily, rosuvastatin 20 mg daily, isosorbide mononitrate 60 mg daily, and acetaminophen as needed for pain. His PMH includes a history of MI, HTN, gout, dyslipidemia, and arthritis. Vital signs: BP 100/60 mm Hg; HR 62 bpm, weight 90 kg. Laboratory findings are within normal limits. Which of the following is the most appropriate option to treat this patient's angina?

    A. Change carvedilol 25 mg twice daily to amlodipine 10 mg daily

    B. Change isosorbide mononitrate to a nitroglycerin patch

    C. Increase carvedilol to 50 mg twice daily

    D. Add ranolazine 500 mg twice daily

11. A 65-year-old patient with continued angina presents to the primary care physician. Home medications include aspirin 81 mg daily, ramipril 10 mg daily, metoprolol 50 mg twice daily, atorvastatin 40 mg daily, nitroglycerin patch 0.8 mg/hr daily, SL nitroglycerin as needed for angina, dofetilide 500 mcg twice daily, and apixaban 5 mg twice daily. PMH includes a history of multiple MI's, a history of PCI with stents 5 years ago, atrial fibrillation, HTN, and dyslipidemia. Vital signs: BP 138/85 mm Hg, HR 58 bpm. LDL 70 mg/dL (1.81 mmol/L). Which of the following is the most appropriate agent to treat this patient's angina?

    A. Increase metoprolol to 100 mg twice daily

B. Add Ranolazine 500 mg twice daily

C. Add amlodipine 5 mg daily

D. Add Diltiazem ER 120 mg daily

12. A 72-year-old patient is getting ready to be discharged after undergoing a CABG procedure for his chronic, refractory angina. PMH includes HTN, CAD, diabetes, and hyperlipidemia. Discharge medications include aspirin 81 mg daily, metformin 500 mg twice daily, carvedilol 12.5 mg twice daily, and rosuvastatin 40 mg daily. Vital signs: BP 140/90 mm Hg, HR 75 bpm. Hemoglobin A1c is 6.5% (0.065; 48 mmol/mol) and LDL is 65 mg/dL (1.68 mmol/L). Which of the following medications should be added to this patient's regimen?

A. Ticagrelor 90 mg twice daily

B. Lisinopril 10 mg daily

C. Ezetimibe 10 mg daily

D. Empagliflozin 10 mg daily

13. Which of the following directly affects myocardial oxygen demand?

A. Myocardial wall tension

B. Presence of anemia

C. Large plaque burden

D. Coronary vasospasm

14. A 64-year-old patient is newly diagnosed with SIHD. PMH includes dyslipidemia. Blood pressure is 126/74 mmHg, HR 68 bpm. LDL is 110 mg/dL (2.84 mmol/L). The following medications are initiated: aspirin 81 mg daily, atenolol 50 mg daily, atorvastatin 80 mg daily, and ramipril 2.5 mg daily. Which of the following medications should also be considered?

A. Clopidogrel 75 mg daily

B. Ranolazine 500 mg twice daily

C. Nitroglycerin SL 0.4 mg PRN

D. Verapamil ER 180 mg daily

15. A 69-year-old female with diabetes complains of midepigastric discomfort that radiates to her jaw. Her symptoms are brought on by gardening and relieved with rest. Which of her symptoms is atypical?

A. Midepigastric discomfort

B. Provocation by gardening

C. Radiation to her jaw

D. Relief by rest

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** The best answer is to initiate and continue aspirin indefinitely as it has been shown to reduce the risk of SVG closure during the first year after CABG surgery. Low-dose rivaroxaban has been evaluated in patients with both stable ASCVD and ACS undergoing CABG with no statistically significant

differences in graft failure found. Therefore, it is not recommended to maintain graft patency. Ticagrelor as a single antiplatelet agent is not recommended post-CABG as the antiplatelet agent of choice. It could be used post-CABG in combination with aspirin in patients who have had a recent stent or an ACS event, but it has not been found to be better than aspirin alone post-CABG in one trial (RKC1). Warfarin would not be indicated post-CABG unless the patient had a specific indication for anticoagulation. Thus, A is the best answer. See section “Pharmacotherapy with CABG”.

2. **C.** When coronary atherosclerotic plaques exceed a critical threshold, typically approximately 70% blockage, the coronary reserve is used at rest to vasodilate the obstructed coronary artery and maintain coronary blood flow. As a result, the ability to adapt to increases in oxygen demand is diminished because coronary flow reserve is exhausted, leading to ischemia. Thus, C is the best answer. See section “Etiology and Pathophysiology”

3. **D.** Older patients, females, and those with diabetes are more likely to experience atypical symptoms of angina. Therefore, D is correct (age 76, history of diabetes). See the “Clinical Presentation” section.

4. **D.** Successful treatment of angina should reduce the frequency of angina episodes as well as the weekly use of sublingual nitroglycerin. Although the patient reports no change in provoking factors nor the frequency or severity of episodes, the increased use of sublingual nitroglycerin may indicate worsening symptoms of angina; D is the best answer. See the “Evaluation of Clinical Outcomes” section.

5. **A.** Current guidelines recommend a BP goal of <130/80 mm Hg; thus, A is correct. Although LDL goals of <70 mg/dL (1.81 mmol/L) may be targeted in “very high-risk” patients (such as those with a history of multiple ASCVD events or 1 major event and multiple high-risk comorbidities), current guidelines recommend the use of high-intensity statins in patients with clinical ASCVD such as this patient or patients who are 40 to 75 years of age and diabetes to reduce LDL by ≥ 50%. Diabetes guidelines recommend a hemoglobin A1c of <7% (0.07; 53 mmol/mol) in select patients and 7% to 9% (0.07-0.09; 53 to 75 mmol/mol) in frail or high-risk patients, not <6.5% (0.065; 48 mmol/mol). While a BMI between 18.5 and 24.9 kg/m^2 is ideal to reduce CV risk, the initial goal of weight management is to lose 5% to 10% of body weight from baseline (Table 33-5).

6. **D.** The best answer is to increase the β-blocker dose, which is a guideline-recommended first-line treatment of angina since the patient is experiencing continued angina and is on a low dose of metoprolol. Additionally, his blood pressure and heart rate are not at target levels and further lowering of BP and HR will improve the myocardial oxygen mismatch and improve his angina. See the “Pharmacotherapy to Relieve Symptoms Recommendations” section and “β-blockers” subsection.

7. **B.** The best answer is to initiate an ACE inhibitor in this patient since he has SIHD and is also post MI. The SIHD guidelines recommend the use of ACE inhibitors in all patients with SIHD who also have HTN, DM, LV dysfunction, or chronic kidney disease, unless contraindicated as well in patients post-MI. See “Angiotensin-Converting Enzyme (ACE) Inhibitors” and “Blood Pressure Management” sections (see Table 33-5).

8. **D.** The correct answer is aspirin 81 mg plus clopidogrel 75 mg daily for at least 6 months in a SIHD who receives a drug-eluting stent during an elective PCI. The guidelines recommend clopidogrel as the $P2Y_{12}$ antiplatelet of choice in SIHD patients undergoing an elective PCI. The correct dose of aspirin should be 75 to 100 mg daily. See the “Pharmacotherapy with PCI” section.

9. **A.** SL nitroglycerin can be used for the treatment of acute angina attacks but also can be used for the prevention or prophylaxis of angina if taken before partaking in an exertional event known to precipitate angina. See Education for clinicians and patients on use of sublingual nitroglycerin (see Table 33-8).

10. **D.** The correct answer in this patient with continued angina while receiving a β-blocker and chronic nitrate with low blood pressure and heart rate is to add ranolazine. Ranolazine provides relief of angina without impacting hemodynamics such as HR, BP, the inotropic state, or increase coronary blood flow. See the “Pharmacotherapy to Relieve Symptoms Recommendations” section and “Ranolazine” subsection.

11. **C.** The patient’s blood pressure is not at the goal of <130/80 mm Hg and since he is continuing to experience angina, amlodipine would be the best agent to add on to his current regimen to control both angina and reduce blood pressure. Ranolazine can be added on to anginal regimens, often as third- or fourth-line options but this patient has a drug-drug interaction with the dofetilide and ranolazine; both of which can increase the QTc interval and predispose this patient to torsades de pointes. In addition, ranolazine will not address this patient’s elevated blood pressure. Metoprolol is not a good option in this patient due to the low heart rate of 58 bpm on the current dose. Lastly, diltiazem is not a good option to add on in this situation since he is already taking another AV nodal blocking agent, metoprolol, and his heart rate is already low. See the “Pharmacotherapy to Relieve Symptoms Recommendations” section.

12. **B**. The addition of an ACE inhibitor should be considered in stable patients post CABG with compelling indications (eg, HFrEF, HTN, DM, and chronic kidney disease). This patient has diabetes, and his blood pressure is not controlled. The use of dual antiplatelet therapy (DAPT) may be considered in some patients post-CABG, such as those with a recent stent ACS presentation. In a patient with stable ischemic heart disease undergoing CABG, DAPT with clopidogrel, but not ticagrelor, could be an option. There is no need for ezetimibe or empagliflozin in this patient since his LDL is < 70 mg/dL (1.81 mmol/L) and hemoglobin A1c is < 7% (0.07; 53 mmol/mol). See the "Pharmacotherapy with CABG" section.

13. **A**. The major determinants of MVO_2 include heart rate (HR), myocardial contractility, and intramyocardial wall tension. Arterial oxygen content is related to hemoglobin concentration and oxygen saturation. Consequently, patients with anemia (low hemoglobin) or hypoxia (low oxygen saturation) have lower than normal oxygen-carrying capacity. Both large atherosclerotic plaque burden inside a coronary artery and coronary vasospasm affect coronary artery oxygen supply. See the "Etiology and Pathophysiology" section.

14. **C**. All patients with SIHD should be prescribed SL nitroglycerin to treat acute symptoms of angina in the absence of contraindications (C is correct). A combination of antianginal therapies is not recommended for the initial management of patients with SIHD; therefore, neither ranolazine nor verapamil is indicated. In the case of verapamil, adding this to beta-blocker therapy (atenolol) may also increase the risk of bradycardia and should be avoided. In the absence of an ACS event or PCI within the preceding 6 to 12 months, DAPT is not indicated. Thus, clopidogrel is incorrect. See Figure 33-2 and section "Antiplatelet Therapy".

15. **A**. Atypical symptoms of angina may consist of mid-epigastric discomfort (A is correct), effort intolerance, dyspnea, and/or excessive fatigue. Radiation to the jaw or left arm (C), provocation by exertion (B), and relief by rest (D) are all typical symptoms of angina and, thus, incorrect. See the "Clinical Presentation" section.

Chapter 34: Acute Coronary Syndrome

Robert J. DiDomenico; Paul P. Dobesh; Shannon W. Finks

KEY CONCEPTS

KEY CONCEPTS

①The cause of acute coronary syndrome (ACS) in more than 90% of patients is the acute rupture, fissure, or erosion of an unstable atherosclerotic plaque followed by subsequent thrombus formation that impairs distal blood flow resulting in acute myocardial ischemia.

②Patients with symptoms of myocardial ischemia suspected of having ACS should undergo risk stratification that incorporates their past medical history, presenting signs and symptoms, 12-lead electrocardiogram (ECG), and cardiac troponin (cTn); dynamic elevation in serial cTn values confirms the diagnosis of myocardial infarction (MI).

③Intravenous (IV) nitroglycerin should be considered to alleviate anginal pain and/or treat acute comorbidities such as uncontrolled hypertension (HTN) or heart failure (HF), oxygen should be administered to patients with hypoxia (oxygen saturation less than 90% [0.90]), and IV morphine may be considered in patients with refractory anginal pain.

④In the absence of contraindications, an oral β-blocker should be initiated for all patients with ACS and continued for 3 years or more to reduce the risk of major adverse cardiac events (MACE); calcium channel blockers (CCBs) may be considered in patients with vasospasm and those refractory to or with contraindications or intolerance to β-blockers.

⑤Reperfusion of the infarct-related artery in ST-segment elevation myocardial infarction (STEMI) with primary percutaneous coronary intervention (PCI) within 90 minutes of first medical contact is preferred to fibrinolytic therapy unless primary PCI cannot be performed within 120 minutes of presentation.

⑥Antiplatelet therapy is a central component to the acute and chronic management of patients with ACS to reduce MACE, frequently includes aspirin plus a $P2Y_{12}$ inhibitor, and requires careful attention paid to the clinical scenario to select the regimen that optimizes efficacy and safety.

⑦Use of parenteral anticoagulant agents (unfractionated heparin, low-molecular-weight heparin [LMWH], fondaparinux, bivalirudin) during hospitalization have the ability to reduce MACE in patients with ACS and requires knowledge of the diagnosis, selected management strategy, and other factors to select the drug and dosing regimen that optimize efficacy and safety.

⑧Dual antiplatelet therapy (DAPT) with aspirin plus a $P2Y_{12}$ receptor inhibitor is indicated for all patients post ACS for a minimum of 12 months regardless of whether the patient is managed with an ischemia-driven approach or if the patient undergoes revascularization.

⑨All patients post-ACS should receive maximally tolerated high-intensity statin therapy to reduce the risk of MACE; patients with low-density lipoprotein cholesterol (LDL-C) of 70 mg/dL (1.81 mmol/L) or greater on maximally tolerated high-intensity statin therapy should be considered for the addition of nonstatin therapies (eg, ezetimibe, proprotein convertase subtilisin kexin 9 [PCSK9] inhibitor).

⑩To reduce the risk of MACE, all post-MI patients should receive oral treatment with an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB) unless contraindicated and a mineralocorticoid receptor antagonist if the left ventricular ejection fraction (LVEF) is 40% (0.40) or less and HF symptoms or diabetes mellitus (DM) are also present.

BEYOND THE BOOK

BEYOND THE BOOK

To better understand the pathophysiology of acute coronary syndrome (ACS), clinical presentation, and the rationale for pharmacotherapy to treat ACS, please watch the videos below. These videos should enhance learner understanding regarding the COLLECT, ASSESS, and PLAN steps in the Patient Care Process.

1. Thrombotic cascade in ACS—Acute coronary syndrome (ACS) pathology—Thrombosis Advisor https://www.youtube.com/watch?v=VIYAAdkOOrk (Duration 1:48 minutes)
2. Acute Coronary Syndrome DETAILED Overview (MI, STEMI, NSTEMI)—Armando Hasudungan https://www.youtube.com/watch?v=TBG9Jw3yd9I (Duration: 24:10)

Learners are encouraged to review Chapter 16: Acute coronary syndrome “ST-elevation myocardial infarction: I can’t handle the pressure level III” in the *Pharmacotherapy Casebook: A Patient-Focused Approach* to practice applying their knowledge to develop a patient-centered care plan for a patient with ACS.

INTRODUCTION

Acute coronary syndrome (ACS) is an acute manifestation of coronary artery disease (CAD) and, for many patients, is the first indication they have CAD. Patients with ACS typically experience an acute reduction in coronary blood flow most often due to a ruptured atherosclerotic plaque and subsequent formation of an intracoronary thrombus. The reduction in coronary blood flow produces myocardial ischemia and, if left untreated, may lead to myocardial infarction (MI).

Patients with ACS typically experience acute chest discomfort similar to those with stable ischemic heart disease (SIHD) but the symptoms are often more severe and prolonged or refractory despite medical interventions. Like patients with SIHD, those experiencing ACS are at risk for complications such as MI, heart failure (HF), ventricular arrhythmias, and death. The spectrum of ACS includes ST-segment elevation myocardial infarction (STEMI), non-ST-segment elevation myocardial infarction (NSTEMI), and unstable angina (UA). The American College of Cardiology (ACC) and the American Heart Association (AHA) have published guidelines for the diagnosis and management of patients with STEMI and non-ST-segment elevation acute coronary syndrome (NSTE-ACS), which includes NSTEMI and UA.[1,2]

EPIDEMIOLOGY

The AHA estimates that every 40 seconds an American will experience an MI.[3] There is a direct relationship between age and the prevalence of both CAD and CAD-related events such as MI. More than 1 million persons are discharged from the hospital annually with a primary or secondary diagnosis of an ACS.[3] MI accounts for more than 70% of these hospitalizations, the majority of cases are the first occurrence of a coronary event.[3] The presentation of MI has changed over the last two decades. Since 2000, the proportion of all patients with MI experiencing STEMI has declined while the proportion experiencing an NSTEMI has increased, the latter representing 74% of patients with MI between 2010 and 2014 in one study.[4] While many patients who experience an MI have symptoms prompting emergent care, an estimated 170,000 Americans will suffer a MI with minimal or no symptoms (eg, “silent MI”) that may go undetected, placing them at high risk for major adverse cardiovascular events (MACE).[3]

Patients who experience ACS are at high risk for developing complications. The 1-year and 5-year mortality rates for patients experiencing MI are estimated at 18% to 23% and 36% to 47% for males and females, respectively.[3] Patients experiencing STEMI have a greater short-term (eg, 30 days) risk of complications, including death, compared to patients experiencing NSTEMI, whereas NSTEMI is associated with a greater long-term (eg, 2 years) risk.[3] In addition to death, patients experiencing ACS are also at risk for developing HF, cardiogenic shock, and ventricular arrhythmias, each of which contributes to the mortality associated with this disease state. Fortunately, declines in STEMI prevalence and overall severity of MI coupled with therapeutic advances have contributed to a reduction in complications associated with ACS globally. For instance, the rate of HF hospitalizations following MI declined more than 60% between 2000 and 2015 and the risk of death has similarly declined.[5] Lower rates of in-hospital death and MACE have been associated with increased utilization of percutaneous coronary intervention (PCI) and optimal medical therapy in patients treated for MI.[6]

Therefore, the use of evidence-based therapies to treat ACS, the focus of this chapter, improves outcomes in these patients and should be prioritized in care plans.

The treatment of ACS is associated with significant healthcare resource utilization and related costs. For patients hospitalized for ACS, the mean and median length of stay were 5.5 and 4 days, respectively, in a recent analysis.[7,8] Frequent hospitalizations and utilization of revascularization therapies (eg, PCI, coronary artery bypass grafting [CABG]) lead to high costs associated with treating patients with ACS. In the United States, the mean cost of treating patients hospitalized for UA was $7,916 (median cost $7,841) while the average cost of hospitalization for MI was $24,695 (median cost $26,749).[9] In fact, MI ranks among the top 10 most expensive conditions treated in the United States.[3] While the adjusted hospitalization cost of treating MI remained relatively unchanged between 2001 and 2011 in one analysis, hospital costs increased by 10% if MI was treated with PCI and approximately 20% if CABG surgery was performed.[8]

ETIOLOGY

① Endothelial dysfunction, inflammation, and the formation of fatty streaks contribute to the formation of atherosclerotic coronary artery plaques, the underlying cause of CAD.[9] The predominant cause of ACS in more than 90% of patients is the acute rupture, fissure, or erosion of an unstable atherosclerotic plaque followed by subsequent thrombus formation that impairs distal blood flow resulting in acute myocardial ischemia. If myocardial ischemia persists sufficiently long, MI can occur. This presentation of MI is classified as a type 1 MI.[10] Less commonly, ACS may occur due to an acute mismatch between oxygen supply and demand (eg, coronary vasospasm, coronary embolism, coronary artery dissection, a concomitant condition that acutely increases oxygen demand). When the latter results in myocardial injury, it is classified as a type 2 MI.[10] Other classifications of MI include patients who suffer cardiac death with symptoms suggestive of myocardial ischemia for whom biomarker detection is not possible (type 3), MI associated with PCI-related myocardial injury (type 4), and MI associated with CABG surgery (type 5).[10]

PATHOPHYSIOLOGY

The "Vulnerable Plaque"

① The basic pathophysiologic process leading to an ACS event typically involves the rupture of an atherosclerotic plaque and subsequent thrombus formation. This thrombus formation produces an abrupt decrease in myocardial blood flow and oxygen supply leading to ischemia and potentially the death of myocytes and infarction.[11] The development of atherosclerotic plaques is complex and discussed in detail in Chapter 32, "Dyslipidemia." The atherosclerotic plaques that produce demand-driven angina in patients with SIHD are different from those that produce an ACS. The atherosclerotic plaques in patients with SIHD typically have thicker fibrous caps, and rarely rupture. The atherosclerotic plaques that rupture in patients with ACS typically have thin fibrous caps and are "vulnerable" to rupture.[12] The plaques in patients with ACS also have a larger cholesterol necrotic core while those in patients with SIHD are more likely to be solidified with calcium deposits. Atherosclerotic plaques that rupture in patients with ACS tend to be "nonobstructive," occluding less than 70% of the luminal diameter. Thus, patients with nonobstructive plaques may not experience angina symptoms prior to plaque rupture due to adequate autoregulation to maintain blood flow and oxygen supply in times of increased myocardial oxygen demand (coronary autoregulation is discussed in Chapter 33, "Stable Ischemic Heart Disease"). Therefore, patients are often unaware they have atherosclerotic plaques until the ACS event occurs.

The fibrous cap of an atherosclerotic plaque is what separates its lipid core from circulating platelets and coagulation factors in the blood. The cap initially is normal arterial intima or thickened intima tissue. As the atherosclerotic plaque grows this is replaced and expanded by fibrous tissue with high amounts of type 1 collagen.[13] In "vulnerable plaques," increased breakdown of collagen in the fibrous matrix and a reduction in collagen production cause the fibrous cap to become thinned and prone to rupture. Inflammatory processes are involved with both mechanisms.

The reduction in collagen production originates from a reduction in the number of secretory smooth muscle cells within the plaque, and a reduction in the synthesis within these cells.[13,14] Alteration of collagen synthesis and breakdown by macrophages and T cells demonstrates the significant role inflammation plays in thinning and weakening of the fibrous cap and increasing the potential for plaque rupture triggering an ACS event.[13–15] Altering the role of these inflammatory processes continues to be an active area of investigation to prevent and treat patients with atherosclerosis and ACS.

A thinning fibrous cap by itself does not usually produce plaque rupture. There is typically a connection to physiological or psychological stress which enhances the likelihood of an acute event.[16,17] Approximately two-thirds of ACS events occur in the morning. This is likely related to circadian rhythm activation of the sympathetic nervous system (SNS) and catecholamine release that produces an increase in heart rate, blood pressure, and vasoconstriction. An increase in catecholamines may occur due to physical and emotional stress. These changes in conjunction with a thin fibrous cap place patients at risk for ruptured atherosclerotic plaque and subsequent ACS.

Plaque Rupture and Clot Formation

①The process of thrombus formation at the site of the ruptured atherosclerotic plaque is complex. Thrombus formation involves platelets and the coagulation cascade. While these two components of thrombus formation are often described separately, they are intertwined and each depends on the other.[18] These components do not contribute equally to thrombus formation in all vascular types. In venous thrombosis, the coagulation cascade dominates thrombus formation and platelets play a more minor role. In arterial thrombosis, such as ACS, platelets dominate, with the coagulation process having less contribution. This is evident by the use of pharmacotherapy to manage thrombosis in each vascular type. While the prevention and treatment of venous thrombosis are managed with anticoagulant agents almost exclusively, patients with arterial thrombosis are treated with two, and sometimes three, antiplatelet agents and typically receive a single anticoagulant agent for a short duration.

Upon plaque rupture, the barrier between the necrotic core of the plaque and blood components is breached.[18] Circulating platelets are initially attracted and adhere to the area of injury. The adhesion of these initial platelets occurs via platelet glycoprotein (GP) VI receptors binding to collagen within the damaged fibrotic cap, as well as platelet GP Ib-IX receptors and von Willebrand factor. Platelets may then be activated by numerous substances including collagen, thrombin, thromboxane A$_2$, adenosine diphosphate (ADP), epinephrine, and serotonin. These substances have different potency in their ability to activate platelets, with thrombin (from the clotting cascade) and collagen being the strongest activators. Each of these activators has individual receptors found on the platelet surface (eg, P2Y$_{12}$ receptor for ADP, protease-activated receptor [PAR]-1 for thrombin).

Once an activator binds to its specific receptor a chain reaction is initiated within the platelet with an influx of calcium leading to multiple changes in the platelet.[18] During platelet activation, the platelet changes shape from a disc-like structure to a polymorphic structure with protruding arms that significantly increases the surface area of the platelet. Granules with high concentrations of platelet activators (eg, thromboxane A$_2$, ADP, serotonin) make their way to the surface of the platelet and release their contents into the circulation. This leads to additional localized activation of platelets that have not adhered to the area of vascular injury. The activated platelet is also the location of the assembly of the tenase and prothrombinase complex that produces most of the activated factors Xa and IIa (thrombin) in the coagulation cascade. Therefore, this represents the interface between platelets and the clotting cascade in thrombosis. Finally, platelet activation leads to the expression of active GP IIb/IIIa receptors.[18] Upon platelet activation, there are approximately 90,000 to 100,000 GP IIb/IIIa receptors, making it the most abundant receptor found on any cell in the body.[18] Through activation, the GP IIb/IIIa receptors undergo a conformational change that exposes the binding site. The main ligand that binds to this receptor is fibrinogen, a linear molecule with a binding site for GP IIb/IIIa on each side. Therefore, each fibrinogen molecule can bind to a GP IIb/IIIa receptor on different platelets, linking those platelets together. The linking of platelets together via the GP IIb/IIIa receptors and fibrinogen is the process of platelet aggregation. Hence, the process of platelet adhesion, activation, and aggregation produce a platelet plug in the area of atherosclerotic plaque rupture.

The platelet plug by itself is rarely enough to significantly occlude myocardial blood flow and oxygen supply.[16] A fibrin meshwork then forms within and on top of the platelet plug that more completely traps cellular components such as red blood cells and produces the abrupt reduction in myocardial blood flow. The formation of this fibrin meshwork involves activation of the clotting cascade.

The initiation of the clotting cascade begins with the interaction and activation of factor VII and tissue factor.[18] Tissue factor is found in endothelial cells, as well as on macrophages at the site of the ruptured fibrous cap. This tissue factor–factor VIIa complex is able to activate small amounts of factor X, which then can activate small amounts of thrombin (factor IIa). The amount of thrombin produced during this initiation phase of coagulation is not enough to promote thrombosis. However, this initial amount of thrombin activates factor VIII. Activated factor VIII (factor VIIIa), with factor IXa (produced from the tissue factor–factor VIIa complex as well as factor XIa), creates the tenase complex on the platelet surface which activates large amounts of factor X. The initial thrombin produced also activates factor V. Activated factor V (factor Va) and activated factor X (factor Xa produced from the tenase complex) create the prothrombinase complex on the surface of the activated platelet where the majority of the thrombin involved in thrombosis is produced. Thrombin is now able to convert fibrinogen into fibrin, which creates the meshwork in the thrombosis and solidifies the clot.

Thrombin also activates factor XIII, which provides additional clot stability, continues the positive feedback with the creation of factors VIIIa and Va, as well as provides significant platelet activation via PAR-1 receptors. The contributions of platelets and the coagulation cascade in thrombus formation in ACS are depicted in Fig. 34-1.

FIGURE 34-1

Role of platelets and coagulation cascade in thrombus formation in ACS. Panel A depicts receptors and mediators of platelet adhesion, activation, and aggregation during acute coronary syndrome (ACS). Panel B depicts components of the coagulation cascade during thrombus formation in ACS. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. Activated coagulation factors are followed by the letter a: II, prothrombin; IIa, thrombin. (TxA2, thromboxane; PAR, protease-activated receptor; GP, glycoprotein; ADP, adenosine diphosphate; COX, cyclooxygenase; PG, prostaglandin; vWF, von Willebrand factor; TF, tissue factor) (*From Ref.*[19].)

Thrombus formation in the area of atherosclerotic plaque rupture produces an abrupt reduction in myocardial blood flow and oxygen supply. This abrupt blockage produces ischemia and, if untreated, potentially infarction which results in myocyte necrosis and cell death.[12,16,17] Therefore, early recognition and prompt initiation of treatment can limit ACS-related sequelae. The progression to infarction and the extent of infarction depends on a number of factors. These may include both the location and size of the thrombus, activity of the endogenous fibrinolytic system, as well as the extent of collateral circulation.[16,17]

Ventricular Remodeling After MI

In the setting of MI, acute and chronic adaptations occur to prevent hemodynamic collapse that may also lead to ventricular remodeling and the development of post-MI complications. Similar to what occurs locally within the infarct-related artery, inflammation at the site of myocardial injury plays a key role in ventricular remodeling. In addition, stimulation of the neurohormonal systems occurs and contributes to this process.

In patients who experience a decrease in cardiac output following MI, stimulation of both the SNS and renin–angiotensin–aldosterone system (RAAS) occurs to compensate for the decrease in cardiac output similar to what is observed in patients with acute and chronic HF (see Chapter 36, "Chronic Heart Failure" and Chapter 37, "Acutely Decompensated Heart Failure"). Activation of the SNS is immediate, resulting in increased contractility, heart rate, and peripheral resistance.[20] However, because the synthesis of components of the RAAS is dependent on an increase in mRNA and protein levels, the response is slower.[20] Stimulation of the RAAS results in sodium and water retention as well as peripheral vasoconstriction in an attempt to maintain adequate hemodynamics and perfusion. Vasopressin and endothelin are also released following MI but play a lesser role.[20]

Following MI, some patients experience chronic hyperactivity of either or both the SNS and RAAS, both of which contribute to adverse cardiac remodeling.[20] Chronic hyperactivation of the SNS leads to desensitization and downregulation of β_1-adrenergic receptors, modification of the excitation-contraction coupling mechanism, ventricular hypertrophy, and further impairment of contractility and cardiac output. Likewise, increased production of both angiotensin II and aldosterone via chronic hyperactivation of the RAAS leads to ventricular hypertrophy. Angiotensin II also increases oxidative stress, the release of inflammatory mediators, and collagen deposition, each of which contributes to myocardial fibrosis, or scarring. While myocardial fibrosis is essential for tissue repair following MI, its development impairs ventricular contraction and elasticity. This can lead to the thinning of the left ventricular wall and eventually to the development of dilated cardiomyopathy.

Complications

Depending on the extent and area of ischemia, various complications are possible in patients with ACS, particularly those with MI, which can manifest hours to weeks after the index event.[21] Electrophysiologic disturbances including ventricular arrhythmias, bradyarrhythmias, and heart block are possible and may occur either in the acute phase of the ischemic event due to electrical instability generated during myocyte destruction or in the recovery phase due to ventricular remodeling. HF is possible depending on the extent of myocardial necrosis and subsequent impairment of ventricular contractility. In fact, approximately 5% to 6% of patients with STEMI develop cardiogenic shock, an acute, severe form of HF associated with hypotension, systemic hypoperfusion, and poor outcomes.[21] Myocardial rupture of the papillary muscle, ventricular septum, or free wall of the ventricle is possible within the first 10 days of infarction due to extensive myocyte necrosis in those areas.[21] Thromboembolism, including stroke, is also possible due to the embolization of left ventricular thrombi that can form due to infarct-related ventricular aneurysm or left ventricular dysfunction. Pericarditis, an autoimmune-mediated inflammation of the pericardium, can occur weeks after an MI, particularly after a large infarct.[21] Mental health can also be impacted as many patients with ACS develop depression during the convalescent period.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Acute Coronary Syndrome

General

- The patient is typically in acute distress and may develop or present with hypertensive crisis, acute HF, cardiogenic shock, or cardiac arrest.

Symptoms

- The classic symptom of ACS is abrupt-onset substernal chest pain or discomfort often described as a squeezing, heaviness, or tightness that persists for 10 minutes or longer. Symptoms may radiate to the arms, shoulders, back, abdomen, or jaw. Nausea, vomiting, diaphoresis, or shortness of breath may also be present.
- Patients likely to present with atypical symptoms include older adults aged 75 years or greater, women, and patients with diabetes mellitus (DM), impaired renal function, and dementia.

Signs

- No physical findings are specific for ACS. Nonspecific findings include S_4 or paradoxical splitting of S_2 on auscultation.
- Patients with ACS may present with signs of acute decompensated HF including jugular venous distention, pulmonary edema, and an S_3 on auscultation.
- Patients with ischemia-related papillary muscle dysfunction may present with a new murmur of mitral regurgitation.
- Patients may also present with arrhythmias, including tachycardia or bradycardia, as well as heart block.
- Hemodynamic abnormalities may include hypertension (HTN) and hypotension or shock.

Laboratory Tests

- Cardiac troponin (cTn, either cTnI or cTnT) is measured at the time of presentation and repeated 3 to 6 hours later (1 to 3 hours later if high-sensitivity cTn assays used) to detect myocardial injury; elevated levels in a patient with ACS symptoms, ischemic changes on ECG, or other diagnostic evidence of ischemia confirm the diagnosis of MI. Additional cTn levels should be obtained beyond 6 hours after symptom onset in patients with intermediate to high-risk features of ACS but normal cTn levels during serial measurements.
- For patients with ACS symptoms who do not have ST-segment elevation on ECG but an elevated cTn, NSTEMI is the appropriate diagnosis. Patients with ACS symptoms but normal cTn may have unstable angina (UA) or an alternative diagnosis.
- Blood chemistry tests are performed with particular attention given to potassium and magnesium, which may affect heart rhythm.
- Serum creatinine (SCr) is measured and creatinine clearance (CrCl) is used to identify patients who are at high risk of morbidity and mortality—dosage adjustments for renally cleared medications may be necessary.
- Baseline complete blood count and coagulation tests (activated partial thromboplastin time [aPTT] or anti-Xa levels, international normalized ratio [INR]) should be obtained; most patients will receive antithrombotic therapy and these tests are useful in monitoring for complications related to antithrombotic therapy, including bleeding.
- Fasting lipid panel.

Other Diagnostic Tests

- The 12-lead ECG is the first step in evaluating a patient with ACS. Patients are risk-stratified into two groups: those with STEMI and those without (NSTE-ACS). Patients with NSTE-ACS may have other ischemic ECG changes including ST-segment depression or T-wave inversion.
- Patients with STEMI and intermediate- to high-risk NSTE-ACS are likely to undergo coronary angiography via a left heart catheterization to diagnose CAD and may be treated with PCI during the procedure.
- An assessment of left ventricular (LV) function via echocardiogram or equivalent modality should be performed to identify patients with LV dysfunction (LV ejection fraction [LVEF] less than 40% [0.40]) who are at high risk of death and candidates for guideline-directed medical therapy and device therapy.
- Selected intermediate-risk patients may undergo coronary computed tomography angiography or stress testing in lieu of invasive coronary angiography
- Selected low-risk patients may undergo early stress testing or coronary artery calcium scanning.

Risk Stratification

- A risk assessment that incorporates the clinical presentation, past medical history, ECG, and cTn should be performed to identify high-risk patients and guide therapeutic interventions. One or more of the validated risk estimators (see Table 34-1) should be used for this purpose and incorporated into clinical decision pathways.

TABLE 34-1

Tools to Assess Risk of Major Adverse Cardiac Events in Patients with Acute Coronary Syndrome

TIMI Risk Score (STEMI)[22]	TIMI Risk Score (NSTE-ACS)[23]	GRACE Risk Score[24]	HEART Score[25]
Component (points)	**Each component worth 1 point**	**Points for each component vary based on value**	**Component (points)**
Age <65 years (0)	Age ≥65 years	Age	History highly suspicious (2)
Age 65-74 years (2)	≥3 CAD risk factors[a]	Killip class	Moderately suspicious (1)
Age ≥75 years (3)	Known CAD[b]	Systolic BP	Slightly suspicious (0)
HTN, DM, or angina[c] (1)	Aspirin use within 7 days	Heart rate	ECG: significant ST
Systolic BP <100 mm Hg (3)	≥2 angina episodes within 24 hours	Serum creatinine	Depression (2), nonspecific
Heart rate >100 bpm (2)	Transient STE or ST depression	Cardiac arrest on admission	Repolarization disturbance (1)
Killip class II–IV (2)	Elevated biomarkers (eg, cTn)	Elevated biomarkers (eg, cTn)	Normal (0)
Weight <67 kg (1)		ST deviation[d]	Age: ≤65 years (2), 45-65 years (1),
Anterior STE or LBBB (1)			<45 years (0)
Time to treatment >4 hours (1)			Risk factors for CAD: ≥3 (2),
			1-2 (1), no risk factors (0)
			Troponin: ≥2x ULN (2),
			1-2x ULN (1), ≤ULN (0)
Calculate point total and determine risk for major adverse cardiac events			
Low risk: 0-3 points	Low risk: 0-2 points	Low risk: <109 points	Low risk: 0-3 points
Intermediate risk: 4-5 points	Intermediate risk: 3-4 points	Intermediate risk: 109-140 points	Intermediate risk: 4-6 points
High risk: ≥6 points	High risk: ≥5 points	High risk: >140 points	High risk: ≥7 points

BP, blood pressure; DM, history of diabetes; cTn, cardiac troponin; ECG, electrocardiogram; GRACE, Global Registry of Acute Coronary Events; HEART, History, Electrocardiogram (ECG), Age, Risk factors, Troponin; LBBB, left bundle branch block; ST, ST-segment; STE, ST-segment elevation; STEMI, ST-segment elevation myocardial infarction; TIMI, thrombolysis in myocardial infarction; ULN, upper limit of normal.

Online calculator available for TIMI Risk Score (STEMI) at: https://www.mdcalc.com/timi-risk-score-stemi

Online calculator available for TIMI Risk Score (NSTE-ACS) at: https://timi.org/calculators/timi-risk-score-calculator-for-ua-nstemi/

Online calculator available for GRACE score at: https://www.outcomes-umassmed.org/grace/acs_risk2/index.html

[a] Risk factors include a family history of coronary artery disease, hypertension, hypercholesterolemia, diabetes, and current smoker.

[b] Prior coronary stenosis ≥50%.

[c] History of angina.

[d] Includes transient ST-segment elevation ≥ 1 mm, ST-segment depression ≥ 1 mm, new T wave inversions ≥ 1 mm, pseudo-normalization of previously inverted T waves, new Q waves, new R wave > S wave in lead V_1, new left bundle branch block.

Signs and Symptoms

② The symptoms and clinical presentation of ACS are similar to those of stable angina (see Chapter 33, "Stable Ischemic Heart Disease"). The "classic" presentation of ACS is an abrupt onset of substernal chest pain often described as a sensation of squeezing, heaviness, or tightness in the chest that radiates to either or both arms or shoulders (radiation to the left side is more common), the neck, or the jaw. Patients with ACS may also experience diaphoresis, nausea, vomiting, and dyspnea. Many patients—as many as one-third—with ACS may present with atypical symptoms that do not include substernal chest pain.[1] Atypical symptoms include epigastric pain, indigestion, stabbing, or pleuritic chest pain, and increasing exertional dyspnea, the latter representing the most common "angina equivalent."[2] Older adults (75 years of age or older), women, and patients with diabetes mellitus (DM), impaired renal function, and dementia are more likely to present with atypical features.[2]

② Features that differentiate ACS from stable angina include symptom severity and duration. Unlike SIHD, patients with ACS often experience symptom durations lasting 10 minutes or longer.[2] New or worsening symptoms or a change in symptom pattern (eg, acute increase in frequency or severity, occurring at rest or minimal exertion, longer duration) may be indicative of ACS.[1,2]

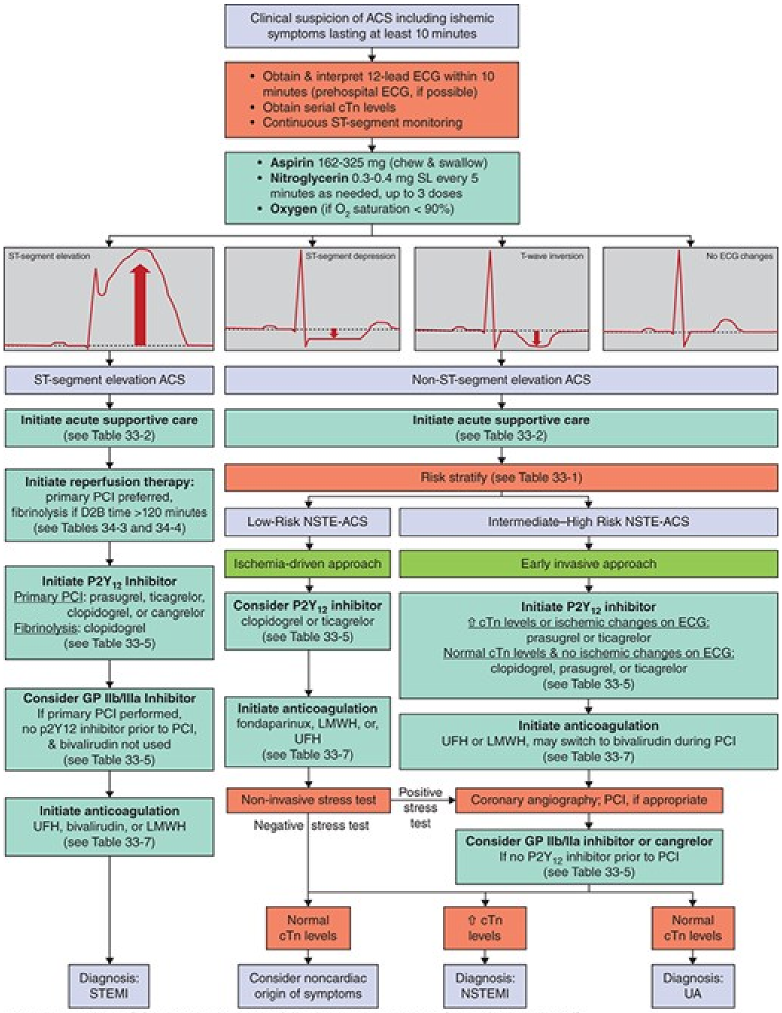
On physical examination, there are no specific findings indicative of ACS. In fact, the physical examination may be normal in many patients. Acute myocardial ischemia can cause an S_4 or paradoxical splitting of S_2 on auscultation, but these are nonspecific findings. Rather, clinicians should evaluate for the presence of complications of MI (eg, HF, new murmur of mitral regurgitation due to papillary muscle dysfunction) which, if present, should expedite the evaluation and therapeutic interventions.[2]

12-Lead Electrocardiogram

② The presenting electrocardiogram (ECG) is critical for expeditious risk stratification and triage of patients presenting with ACS. Patients with possible ACS should have a 12-lead ECG performed and interpreted within 10 minutes of presentation to an emergency department (ED).[2] Ideally, a 12-lead ECG should be performed by emergency medical services (EMS) providers and communicated to the ED staff prior to hospital arrival in order to expedite reperfusion, if necessary.[1] Electrocardiographic changes suggestive of acute ischemia include ST-segment elevation or ST-segment depression of 0.05 mm or greater and T-wave inversion of at least 1 mm in at least two contiguous leads (Fig. 34-2).[2,10] Except for leads V_2-V_3 where greater ST-segment elevation is required, when ST-segment elevation of at least 1 mm is present in patients suspected of having ACS, the presumptive diagnosis of STEMI is made and the patient should be considered for emergent reperfusion therapy (Fig. 34-2).[1,10] In addition, the presence of a new left bundle–branch block (LBBB) in patients suspected of having ACS is strongly suggestive of acute MI and has been considered a STEMI equivalent.[1] However, because new LBBB occurs infrequently, a prior 12-lead ECG should be reviewed, if available, to determine if the LBBB is new or old. Patients with a high suspicion of ACS but with a normal ECG on presentation should have serial ECGs performed (eg, every 15-30 minutes for the first hour) to detect ischemic changes.[2] In approximately 1% to 6% of patients with ACS, often those with occlusions of the left circumflex or right coronary arteries, the 12-lead ECG may be normal or "electrically silent." Therefore, appropriate evaluation and risk stratification for patients with ACS must incorporate the evaluation of the patient's medical history, presenting symptoms, ECG findings, and biomarkers.

FIGURE 34-2

Evaluation and Initial Management of Patients with Suspected Acute Coronary Syndrome (ACS).



Clinical suspicion of ACS including ischemic symptoms lasting at least 10 minutes
• Obtain & interpret 12-lead ECG within 10 minutes (prehospital ECG, if possible)
• Obtain serial cTn levels
• Continuous ST-segment monitoring
• Aspirin 162-325 mg (chew & swallow)
• Nitroglycerin 0.3-0.4 mg SL every 5 minutes as needed, up to 3 doses
• Oxygen (if O2 saturation < 90%)
ST-segment elevation
ST-segment depression
T-wave inversion
No ECG changes
ST-segment elevation ACS
Non-ST-segment elevation ACS
Initiate acute supportive care (see Table 33-2)
Initiate acute supportive care (see Table 33-2)
Initiate reperfusion therapy: primary PCI preferred, fibrinolysis if D2B time >120 minutes (see Tables 34-3 and 34-4)
Risk stratify (see Table 33-1)
Low-Risk NSTE-ACS
Intermediate–High Risk NSTE-ACS
Ischemia-driven approach
Early invasive approach
Initiate P2Y12 Inhibitor Primary PCI: prasugrel, ticagrelor, clopidogrel, or cangrelor Fibrinolysis: clopidogrel (see Table 33-5)
Consider P2Y12 inhibitor clopidogrel or ticagrelor (see Table 33-5)
Initiate P2Y12 inhibitor ⇧ cTn levels or ischemic changes on ECG: prasugrel or ticagrelor Normal cTn levels & no ischemic changes on ECG: clopidogrel, prasugrel, or ticagrelor (see Table 33-5)
Consider GP IIb/IIIa Inhibitor If primary PCI performed, no p2Y12 inhibitor prior to PCI, & bivalirudin not used (see Table 33-5)
Initiate anticoagulation fondaparinux, LMWH, or, UFH (see Table 33-7)
Initiate anticoagulation UFH or LMWH, may switch to bivalirudin during PCI (see Table 33-7)
Initiate anticoagulation UFH, bivalirudin, or LMWH (see Table 33-7)
Non-invasive stress test
Positive stress test
Coronary angiography; PCI, if appropriate
Negative stress test
Consider GP IIb/IIa inhibitor or cangrelor If no P2Y12 inhibitor prior to PCI (see Table 33-5)
Normal cTn levels
⇧ cTn levels
Normal cTn levels
Diagnosis: STEMI
Consider noncardiac origin of symptoms
Diagnosis: NSTEMI
Diagnosis: UA

Cardiac Troponin

The cardiac troponins (cTn) are part of the contractile apparatus of myocardial cells and are the most sensitive and specific biomarkers for detecting myocardial injury.[2,10] Within 2 to 4 hours of myocyte injury or necrosis, these proteins are released into the bloodstream resulting in elevated blood levels (exceeding the 99th percentile of the upper reference limit).[2,10] The emerging high-sensitivity cTn assays are capable of measuring relatively low concentrations much earlier in the clinical course of myocardial injury that could not be detected with traditional cTn assays. The use of high-sensitivity cTn assays likely increases the frequency of NSTEMI diagnosis. Elevations in cTn may persist for several days, and as long as 2 weeks.[2]

② There are several nonischemic causes of myocardial injury (eg, HF, myocarditis, Takotsubo syndrome, chronic kidney disease) that result in elevated cTn, particularly if high-sensitivity cTn assays are used.[2,10] Therefore, clinical context is required to establish the diagnosis of ACS. Myocardial injury is considered acute if there is a dynamic rise and/or fall by 20% or more in serial cTn values.[10] In contrast, when using a high-sensitivity cTn assay, the absolute change (in ng/L), rather than a relative change, increases diagnostic accuracy and may be useful in distinguishing an MI from other causes of cTn elevation.[10] Attention must be paid to the units of measure between traditional and high-sensitivity cTn; they are not interchangeable. When an acute myocardial injury is detected (eg, the dynamic elevation of cTn) in a patient presenting with ACS symptoms, ischemic changes on ECG, or other diagnostic evidence of ischemia (eg, imaging that demonstrates loss of myocardium or new regional wall motion abnormality, coronary thrombus detected during angiography or autopsy), the diagnosis of MI is appropriate.[10] Classification of MI is made based on the presenting ECG findings. For patients with dynamic cTn elevations whose presenting ECG demonstrated ST-segment elevation of at least 1 mm in two contiguous leads or new LBBB, the diagnosis of STEMI is confirmed.[10] In contrast, for patients with symptoms of ACS without at least 1 mm ST-segment elevation on the ECG at presentation but with a dynamic elevation of cTn, the diagnosis of NSTEMI is appropriate.[2,10] Patients with symptoms consistent with ACS but in whom the cTn is not elevated may have UA or an alternative diagnosis.[10]

Given that dynamic changes in cTn are needed to establish the diagnosis of MI, serial cTn levels should be obtained when the patient presents to the ED and again 3 to 6 hours after symptom onset (1-3 hours later if using high-sensitivity cTn).[2,26] If the time of symptom onset is unclear from the patient's history, the time of presentation to the ED should be considered the time of symptom onset.[2] For patients with intermediate- to high-risk features of ACS (eg, ECG changes, clinical presentation) but normal cTn values during serial measurements, an additional measurement of cTn after the 6 hours (3 hours if using high-sensitivity cTn) may be warranted.[2,26]

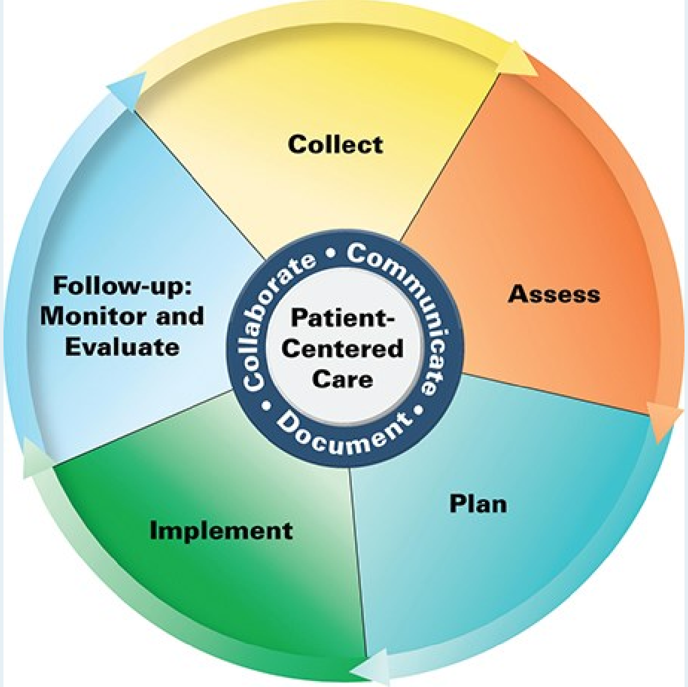
Risk Stratification

② For patients with ACS, acute risk stratification is essential to determine which patients may benefit from reperfusion therapy, an early invasive approach, or medical management (Fig. 34-2).[1,2] Initial evaluation of risk should include the clinical presentation, past medical history, and both ECG and cTn upon presentation. For example, because STEMI has the highest short-term risk of death, patients with ACS who present with significant ST-segment elevation on ECG should be considered for emergent reperfusion therapy; confirmation of elevated cTn should not delay treatment.

Several risk scoring tools have been developed that predict both short-term and long-term event rates, such as mortality, in patients with ACS (Table 34-1).[22–25] These tools have been well-studied and can be easily applied in the clinical setting. Each of the risk assessment tools incorporates the patient's symptoms, past medical history, ECG, and cTn, while the Global Registry of Acute Coronary Events (GRACE) score also includes additional clinical indicators. For each risk estimator, there is a linear relationship between increasing score and the risk of MACE. For example, in patients with NSTE-ACS, the incidence of MACE through 14 days was 4.7% to 8.3%, 13.2% to 19.9%, and 26.2% to 40.9% in the low (Thrombolysis in Myocardial Infarction [TIMI] risk score 0-2), intermediate (TIMI risk score 3-4), and high (TIMI risk score 5-7) risk groups, respectively.[23] Compared to both the TIMI and GRACE risk estimators, the History, ECG, Age, Risk factors, and Troponin (HEART) score is better at identifying patients who present to the hospital with suspected ACS at low risk of MACE.[27] While this prognostic information is useful, the ability of the risk scoring tools to identify patients with ACS who may benefit from specific therapeutic interventions described below makes them particularly useful in the development of the treatment plan.

PATIENT CARE PROCESS

Patient Care Process for Acute Coronary Syndrome



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Description of chest discomfort and/or related symptoms (eg, quality, location, severity, radiation, precipitating factors, palliative measures, time of onset, duration of symptoms)
- Patient medical (personal and family) and social histories (eg, tobacco/ethanol, drugs of abuse [eg, cocaine])
- Current medications with particular attention to phosphodiesterase-5 inhibitors, over-the-counter medications (eg, aspirin-containing medications), and herbals/dietary supplement use
- History of allergy or intolerance to medications
- Objective data
    - Blood pressure, heart rate, respiratory rate, height, weight, O_2-saturation, physical exam
    - Labs: cTn, Scr, potassium, hemoglobin, platelets, lipid profile
    - Diagnostic tests: 12-lead ECG; coronary angiogram and stress testing as necessary

Assess

- Description of chest discomfort to determine differential diagnosis and classification of ACS
- Presence of provoking factors (eg, exertion, mental/emotional stress, tachyarrhythmia, high adrenergic state including the use of stimulant medications, exposure to cold)
- Presence/control of risk factors for CAD (eg, HTN, dyslipidemia, DM, smoking, obesity, family history of premature CAD)
- Presence of ACS-related complications (eg, HF, cardiogenic shock, arrhythmias, heart block, stroke)
- Previous/recent revascularization procedures (eg, PCI with/without stenting, CABG surgery)

- Presence of ST-segment elevation or equivalent on 12-lead ECG
- Risk for major adverse cardiac events (MACE) (eg, perform risk stratification [see Table 34-1])
- Contraindications or intolerance to medications used to treat/prevent angina symptoms and MACE
- Barriers that may impair adherence to the care plan

Plan[*]

- Initiate antithrombotic therapy to treat and prevent intracoronary thrombosis as well as drug therapy to alleviate angina symptoms and prevent MACE including specific drug(s), dose, route, frequency, and duration (see Figs. 34-2 and 34-3; Tables 34-2–34-5, 34-7, and 34-8).
- Monitoring parameters: efficacy (eg, resolution of signs and symptoms of angina and ACS-related complications) and adverse effects; frequency and timing of follow-up (see Table 34-10)
- Patient education: purpose of treatment, lifestyle modifications, planned procedures, drug-specific information (eg, indication, dose, route, frequency, adverse effects)
- Self-monitoring for recurrent angina symptoms, signs and symptoms of ACS-related complications, adverse effects, when to seek emergency medical attention
- Address barriers to adherence to medications and lifestyle modification
- Referrals to other providers (eg, primary care provider, endocrinologist, dietician, smoking cessation)

Implement[*]

- Provide patient education regarding all elements of the treatment plan as described above.
- Use motivational interviewing and coaching strategies to maximize adherence.
- Schedule follow-up (eg, usually within 1-2 weeks but no later than 6 weeks after discharge).

Follow-Up: Monitor and Evaluate

- Presence of angina symptoms, exercise tolerance, presence/control of CAD risk factors, presence/control of ACS-related complications
- Appropriate use and doses of evidence-based pharmacotherapy for ACS
- Presence of adverse effects and drug–drug interactions
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patients, caregivers, and other healthcare professionals.*

TREATMENT

Treatment decisions for patients with ACS are made based on the initial and ongoing risk stratification (Fig. 34-2). Rapid identification and delineation of ACS subtype (STEMI, NSTE-ACS) are imperative as treatment goals and timeframes for intervention differ slightly based on the clinical presentation and subsequent risk of death or complications from the index event (eg, patient with STEMI). When ACS is suspected, the patient should be immediately referred to an ED, chest pain unit, or equivalent facility for evaluation which should include 12-lead ECG and cTn such that expeditious treatment can be initiated.[1,2] Patients with possible ischemic symptoms, particularly if high-risk features (persistent chest pain, severe dyspnea, syncope or presyncope, or palpitations) are present, should be educated to activate the EMS system (eg, call 9-1-1) and seek transport via ambulance.

EMS personnel are equipped to treat cardiac arrest should it occurs and can initiate reperfusion therapy.

Desired Outcomes

In patients with ACS, treatment is aimed at achieving both short-term and long-term outcomes. Desired short-term outcomes in a patient with ACS are as follows: (a) early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA); (b) prevention of death and other MI complications; (c) prevention of coronary artery reocclusion; and (d) relief of ischemic chest discomfort. Long-term goals are control of CAD risk factors, prevention of additional MACE, including reinfarction, stroke, and HF, and improvement in quality of life.

General Approach to Treatment

The general treatment approach to ACS includes rapid diagnostic triage to determine an appropriate management strategy (Fig. 34-2). Patients with STEMI are of the highest priority and should be emergently referred to the cardiac catheterization lab for primary PCI with the goal of mechanically restoring blood flow to the infarct-related artery as quickly as possible. Patients with NSTE-ACS will undergo additional risk stratification to determine the best approach, which is usually an early invasive approach (eg, PCI) for intermediate- and high-risk patients or a more conservative, ischemia-guided management plan without planned PCI for those with either the lowest risk for coronary event or contraindications to the invasive procedure itself (Fig. 34-2). Regardless of treatment strategy planned (early invasive approach or ischemia-guided approach), general treatment measures for intermediate- and high-risk patients include admission to the hospital, oxygen administration (if oxygen saturation is <90% [0.90]), bed rest with continuous multi-lead ECGmonitoring for arrhythmias and ischemia, frequent measurement of vital signs, ischemic pain relief, and prompt initiation of antithrombotic therapy.

Acute Supportive Care

Historically, clinicians and educators have used the mnemonic MONA (Morphine, Oxygen, Nitroglycerin, Aspirin) as a reminder for acute supportive care interventions to be considered in patients with ACS. However, in recent years, recommendations for the routine use of some of these therapies (eg, morphine, oxygen) have been tempered. Further, MONA ignores other potentially useful interventions to consider in the early phase of ACS treatment. Thus, the mnemonic THROMBINS$_2$ (Thienopyridine, Heparin, Renin-angiotensin-aldosterone system, Oxygen, Morphine, β-blocker, Intervention [eg, PCI], Nitroglycerin, Statin/Salicylate [eg, aspirin]) has been developed as a more contemporary reminder for early interventions to consider in patients with ACS.[28] Acute supportive therapies used to treat patients with ACS are summarized in Table 34-2.

TABLE 34-2

Acute Supportive Care Medications Initiated During the Initial 24 Hours of ACS Treatment

Drug	Indication (Class of Recommendation)[a]	Contraindication/Caution	Dose/Administration	Adverse Effects
Morphine	Refractory pain (IIb)	Known hypersensitivity Hypotension Bradycardia Lethargic or moribund patient	STEMI: 4-8 mg IV × 1 (lower dose in older patients), then 2-8 mg IV every 5-15 minutes PRN NSTE-ACS: 1-5 mg IV every 5-30 minutes PRN	Constipation, nausea, vomiting, hypotension, respiratory depression
Oxygen	Oxygen saturation <90% [0.90] (I)	Chronic obstructive pulmonary disease Carbon dioxide retention	2-4 L/min, increasing rate and/or changing to face mask PRN	Increased coronary vascular resistance, decreased coronary blood flow, increased mortality
Nitroglycerin	Angina (I)	SBP less than 90 mm Hg	SL: 0.3-0.4 mg every 5 minutes, up to	Flushing, headache,

	Uncontrolled hypertension (I) Acute heart failure (I)	or greater than 30 mm Hg below baseline Avoid if recent PDE$_5$ inhibitor use: ◦ Avanafil: within 12 hours ◦ Sildenafil: within 24 hours ◦ Vardenafil: within 24 hours ◦ Tadalafil: within 48 hours Use with caution if RV infarct suspected Avoid abrupt cessation of IV nitroglycerin; wean gradually	3 doses PRN IV: 10 mcg/min titrated to symptom relief and desired blood pressure	hypotension, tachycardia
β-blockers	All patients without contraindications (I) *Associated with mortality reduction, especially in patients with HFrEF*	Signs of heart failure Low cardiac output state Risk factors for cardiogenic shock: ◦ Age 70 years or greater ◦ SBP less than 120 mm Hg ◦ Sinus tachycardia (HR greater than 110 bpm) ◦ Sinus bradycardia (HR less than 60 bpm) ◦ Killip class III ◦ Prolonged time from symptom onset High-grade AV block Active asthma or reactive airway disease	Carvedilol 6.25 mg twice daily; target dose is 25 mg twice daily as tolerated Metoprolol ◦ Oral: 25-50 mg every 6-12 hours for 2-3 days, then once (metoprolol succinate) or twice daily (metoprolol tartrate); target dose is 200 mg daily ◦ IV: 5 mg every 5 min as tolerated up to 3 doses, titrated to BP and HR; should only be considered if BP is uncontrolled or refractory symptoms Continue indefinitely in patients with concomitant HFrEF Other β-blockers may be considered; in patients with HFrEF, use either metoprolol succinate, carvedilol, or bisoprolol	Hypotension, heart failure, bradycardia, cardiogenic shock, AV block, exacerbation of asthma or reactive airway disease
Calcium channel blockers	Angina, normal LVEF, and contraindication or intolerance to	Signs of heart failure Low cardiac output state Risk factors for	Diltiazem 120-360 mg/day orally[b] Verapamil 240-480 mg/day orally[b] Amlodipine 5-10 mg orally once daily	Hypotension, Diltiazem and verapamil: heart failure, cardiogenic shock, bradycardia, AV block

	β-blocker (I) Angina refractory to β-blocker and normal LVEF (I) Coronary vasospasm (I)	cardiogenic shock: ○ Age 70 years or greater ○ SBP less than 120 mmHg, sinus tachycardia (HR greater than 110 bpm) ○ Sinus bradycardia (HR less than 60 bpm) ○ Killip class III ○ Prolonged time from symptom onset High-grade AV block	Nicardipine 60-120 mg/day orally[b] Nifedipine ER 30-120 mg orally once daily	

[a] Dose and frequency may differ based on formulation.

[b] AHA/ACC class of recommendations: I, benefit far outweighs the risk, treatment should be administered; IIb, the benefit is equal to or exceeds the risk, additional studies with broad objectives are needed, treatment may be considered.

AV, atrioventricular; BP, blood pressure; ER, extended-release; HFrEF, heart failure with reduced ejection fraction; HR, heart rate; IV, intravenous; PDE5, phosphodiesterase-5; PRN, as needed; RV, right ventricular; SBP, systolic blood pressure.

Data from References [1,2,29].

Nitroglycerin

Nitrates, including nitroglycerin, are effective anti-ischemic medications and are routinely recommended as part of the initial management of patients with ACS.[1,2] Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation. Venodilation, the predominant effect, decreases preload, reducing ventricular wall tension, and myocardial oxygen demand. The effects on arterial vasodilation are less prominent but may lower systemic vascular resistance and blood pressure at higher doses, thus reducing myocardial oxygen demand. Nitrates also dilate coronary arteries and increase collateral blood flow.

However, the rationale for treating ACS patients with nitrates is extrapolated from an understanding of the pathophysiology of ACS, pharmacology of nitrates, numerous uncontrolled studies, and clinical experience—not their ability to reduce MACE.[2] In the reperfusion era, there is a paucity of data demonstrating that nitrate administration to patients with ACS is effective in providing symptom relief or reducing the incidence of MACE. In two large studies of patients with suspected MI, neither IV nitroglycerin (for 24 hours) followed by daily transdermal nitroglycerin nor daily isosorbide mononitrate reduced the incidence of MACE.[30,31] Postinfarction angina and cardiogenic shock were lower with the IV followed by transdermal nitroglycerin approach but not with the isosorbide mononitrate strategy. The use of IV sodium nitrite in 229 patients with STEMI treated with primary PCI had no effect on infarct size.[32]

③ Because nitroglycerin is effective in relieving angina symptoms, it is often utilized in patients with ACS with ongoing angina who are not hypotensive.[1,2] The recommended use for nitroglycerin in patients with ACS is provided in Table 34-2. Initially, SL nitroglycerin should be administered every 5 minutes for up to three doses as needed for angina. For patients with persistent angina despite SL nitroglycerin, IV nitroglycerin should be considered, particularly in patients with uncontrolled HTN or evidence of HF on presentation. Because nitroglycerin dilates coronary arteries, it is useful in treating ACS related to vasospasm, particularly if cocaine intoxication is thought to be contributory. In fact, in patients with cocaine-induced chest pain, IV nitroglycerin is often the initial anti-ischemic medication recommended, especially if uncontrolled HTN is present.[33] Intravenous nitroglycerin should be continued until symptoms have resolved, blood pressure is controlled, and HF symptoms (if present) have subsided. Hemodynamic tolerance to IV nitroglycerin can occur within 8 to 12 hours, requiring higher doses with prolonged therapy. The most significant adverse effects of nitrates are flushing, headache, hypotension, and tachycardia. Because a synergistic reduction in blood pressure can occur leading to hypotension, nitrate administration is contraindicated in patients who have recently taken oral phosphodiesterase-5 inhibitors (Table 34-2).[1,2,34]

Morphine

Intravenous morphine is a potent analgesic and anxiolytic agent that also causes venodilation and increases vagal tone which reduces heart rate.[1,2] The analgesic and anxiolytic effects may improve patient comfort while the hemodynamic effects may reduce oxygen demand thereby making IV morphine an attractive treatment option in patients with ACS. However, randomized clinical trials have not been conducted to determine the optimal dose nor evaluate the safety and efficacy of IV morphine in patients with ACS.

The safety of routinely using IV morphine to treat ACS has been recently questioned. Patients treated for ACS with IV morphine had higher rates of in-hospital death, MACE, and bleeding. Studies evaluating IV morphine to treat ACS have high risk of bias, contributing to low confidence in the observed outcomes.[35]

A proposed mechanism for the adverse outcomes associated with IV morphine in patients with ACS is the presence of a drug–drug interaction with $P2Y_{12}$ inhibitors. Morphine stimulates opioid receptors in the GI tract leading to inhibition of gastric emptying, which may slow the absorption of the antiplatelet agent.[36] Additionally, common side effects of morphine include nausea and vomiting. The coadministration of IV morphine and $P2Y_{12}$ inhibitors prolongs the time to peak concentrations, decreases total drug exposure, and produces less platelet inhibition.[36]

③ There is uncertainty regarding the role of IV morphine in patients with ACS. In patients with STEMI, current guidelines state that IV morphine is the drug of choice for pain relief but do not provide a class recommendation.[1] In NSTE-ACS, the use of IV morphine is recommended only in patients refractory to treatment with other anti-ischemic medications (Class IIb recommendation).[2] If IV morphine is used to treat patients with ACS, doses between 1 and 5 mg every 5 to 30 minutes are recommended (Table 34-2).[1,2] While nausea and vomiting are common, the most serious adverse effects to monitor are hypotension and respiratory depression.

Oxygen

③ Although routine oxygen is often administered to patients with ACS, it should be reserved for a minority of patients, particularly those with oxygen saturation less than 90% [0.90].[1,2] The routine use of oxygen may adversely affect patients with ACS by increasing coronary vascular resistance and reducing coronary blood flow.[1,2] The routine use of supplemental oxygen to patients treated for MI was of no benefit with signals suggesting infarct size may be increased.[37]

β-Blockers

Because β-blockers not only possess beneficial anti-ischemic effects but also lower the risk of MACE, their use is recommended for all patients with ACS without contraindications.[1,2] β-blockers antagonize the β_1-adrenergic receptors causing a decrease in heart rate, contractility, blood pressure, and, subsequently, myocardial oxygen demand. Additionally, the reduction in heart rate increases diastole, prolonging myocardial perfusion and filling time. β-blockers increase coronary blood flow to the ischemic myocardium by increasing coronary collateral resistance, preventing the shunting of blood away from ischemic areas.[19] The reduction in myocardial oxygen demand coupled with improved coronary blood flow to ischemic areas make β-blockers effective anti-ischemic medications in patients with ACS.

The anti-ischemic effects described above also contribute to the reduction in risk of MACE observed in patients with ACS treated with β-blockers. The risk of reinfarction and post-infarction angina is reduced in patients with MI treated with β-blockers.[38,39] Additionally, β-blockers improve survival in patients with MI, although this benefit has been questioned in recent years. Many β-blocker trials in MI that demonstrated a mortality benefit were conducted in the pre-reperfusion era. A contemporary trial conducted in patients with MI during the reperfusion era, the use of early IV followed by oral metoprolol[40] was associated with reductions in reinfarction, ventricular fibrillation, and arrhythmic death.[40] However, the primary composite endpoint (death, reinfarction, ventricular fibrillation, or cardiac arrest) was not significantly different from placebo and the risk of developing shock, including cardiogenic shock, was significantly increased. Consistent with this theme, the evaluation β-blockers in MI had a modest mortality benefit for studies conducted during the pre-reperfusion era but no benefit was observed in studies completed during the reperfusion era.[38] Some of the uncertainty regarding mortality stems from variations in the duration of therapy and follow-up duration in many of the trials. β-blockers had no influence on the odds of death in short-term trials (up to 6 weeks of treatment) but were associated with a 23% lower risk in long-term trials (treatment durations of 6-48 months).[39] In a recent observational study of patients with MI, 5-year mortality was approximately 30% lower for patients treated with β-blockers at hospital discharge; however, the benefits were no longer significant for those continuing therapy beyond one year.[41,42] Consequently, at least one international guideline recommends initiating a discussion with patients who are post-MI with normal left ventricular ejection fraction (LVEF greater than 40% [0.40]) regarding the risks and benefits of continuation beyond 12 months based on recent evidence.

④ Although the mortality benefit of β-blockers in the reperfusion era is uncertain, because they reduce the risk of MI, angina, and arrhythmias, in the absence of contraindications, current ACC/AHA guidelines recommend the initiation of oral β-blockers within the first 24 hours of presentation and continuation of therapy for at least 3 years (Table 34-2).[1,2,29] For patients with ACS and concomitant left ventricular dysfunction (LVEF less than 40% [0.40]), β-blocker therapy is often lifelong.[1,29] Although several β-blockers have been studied in the setting of ACS, the most commonly used agents are metoprolol and carvedilol largely due to the mortality benefit associated with their use in the treatment of HF, a common complication of ACS.

The most serious adverse effects observed in patients with ACS treated with β-blockers include HF, hypotension, bradycardia, and cardiogenic shock.[40] Therefore, in patients with evidence of or risk of developing these complications, β-blocker therapy should be withheld and initiation reassessed later during hospitalization.[1,2] Advanced age (70 years or older), presenting systolic blood pressure less than 120 mm Hg, sinus tachycardia (heart rate greater than 110 bpm) or bradycardia (heart rate less than 60 bpm) upon presentation, Killip class III (eg, pulmonary edema), and a prolonged time from symptom onset are patient characteristics associated with an increased risk of cardiogenic shock for whom β-blocker initiation should be postponed.[1,2,40] While β-blocker initiation should be avoided in patients with ACS and decompensated HF due to left ventricular dysfunction, the initiation of β-blocker therapy once HF symptoms have been stabilized and prior to discharge is safe, has been associated with lower mortality, and should be considered for all patients with ACS and compensated HF with reduced ejection fraction (HFrEF).[2,43] For patients with ACS and acute intoxication with cocaine or methamphetamine, β-blockers should be avoided unless a concomitant coronary vasodilator is also used to minimize the risk of causing or potentiating coronary vasospasm via unopposed α_1-adrenergic stimulation.[2,33,44] Because early initiation of IV β-blockers has been associated with an increased risk of HF and cardiogenic shock, parenteral therapy should be reserved for patients with STEMI who have acute, uncontrolled HTN or refractory symptoms and no contraindications.[1,29]

Calcium Channel Blockers

Calcium channel blockers (CCBs) possess beneficial anti-ischemic effects and are recommended for some patients with ACS, particularly those who are unable to take β-blockers.[1,2] CCBs cause arterial vasodilation, including coronary vasodilation, decreasing peripheral resistance, afterload, blood pressure, and myocardial oxygen demand.[19] All CCBs are also negative inotropes. However, because dihydropyridine (DHP) CCBs are potent peripheral vasodilators, they cause a baroreceptor-mediated increase in sympathetic activity that negates their negative inotropic effect.[19] Non-DHP CCBs decrease sinoatrial node activity and slow atrioventricular node conduction resulting in a decreased heart rate.[19]

④ Although CCBs are effective as anti-ischemic agents, reports of harm, lack of consistent benefit in clinical trials, and the data supporting β-blockers have narrowed the indications for CCBs in patients with ACS. In a systematic review, CCBs had no effect on mortality, MI, or recurrent MI in patients treated for ACS.[42] Consequently, current guidelines recommend non-DHP CCBs (eg, diltiazem, verapamil) to treat angina symptoms in patients with ACS who have a contraindication, have an intolerance, or are refractory to β-blockers in the absence of left ventricular dysfunction, risk factors for cardiogenic shock, and atrioventricular conduction defects (Table 34-2).[1,2] Because of their ability to dilate coronary arteries, long-acting CCBs are recommended in patients with ACS with known or suspected vasospasm.[2] However, if vasospasm is secondary to cocaine intoxication, the use of CCBs should be considered only after treatment with IV nitroglycerin and benzodiazepines.[33,44] Although long-acting formulations may be reasonable, immediate-release nifedipine should be avoided as it has been associated with increased mortality risk in patients with CAD, including those with

ACS.[2,45] The most common adverse effects associated with the use of non-DHP CCBs in patients with ACS include heart block, bradycardia, hypotension, and GI disturbances.

Treatment Strategies in STEMI

The widespread use of reperfusion during ACS is responsible for the dramatic decrease in MI-related mortality over the past three decades in the United States.[46] Reperfusion strategies include fibrinolysis and mechanical intervention via PCI with or without stenting, both with the aim of restoring blood flow to the infarct-related artery. Appropriate choice and timing of reperfusion in ACS to facilitate revascularization are critical in STEMI to improve outcomes. Strategies to reduce delays in reperfusion include prehospital assessment of the initial ECG by EMS, early anti-ischemic medication administration, and transport to a hospital with PCI-capable facilities.

Primary PCI

⑤ In STEMI, the degree of myonecrosis is curvilinear, with the maximum amount of damage occurring in the first few hours of infarction.[47] Therefore, prompt efforts to restore blood flow to the infarct-related artery are paramount. During PCI, mechanical reperfusion is performed using intracoronary balloons, stents, and other devices. The reader is referred to Chapter 33, "Stable Ischemic Heart Disease," for a more detailed description of both coronary angiography and PCI. Compared to reperfusion with fibrinolysis, primary PCI improves survival, establishes consistent revascularization to the infarct-related artery, significantly reduces the risk of stroke and intracranial hemorrhage, and reduces reinfarction and recurrent ischemia. However, the mortality benefit of primary PCI over fibrinolysis is lost when door-to-balloon time exceeds 120 minutes.[48] More rapid performance of primary PCI can result in superior clinical outcomes for patients with STEMI.[1,49,50] In patients with STEMI treated with primary PCI, the risk of in-hospital death was increased by more than 40% when the door-to-balloon time was more than 90 minutes compared to 90 minutes or less.[51] In the United States, quality improvement programs have reduced mean door-to-balloon times from 120 minutes to 87 minutes, decreasing the in-hospital mortality rate from 8.3% to 6.6%.[52] Therefore, early reperfusion with primary PCI is of utmost importance and is preferred by guidelines for patients presenting with STEMI, with the goal of reperfusion within 90 minutes from the time of first medical contact.[1] However, in the United States, only 39% of all hospitals can perform PCI.[53] Given the benefits of primary PCI, the patients presenting with STEMI to a hospital unable to perform PCI should be transferred to a PCI-capable hospital to achieve reperfusion within 120 minutes of the first medical contact.[1] Every minute delay results in additional myocardial cell damage that may be irreversible. Patients with STEMI undergoing primary PCI also require adjunctive antiplatelet and anticoagulant therapy which is discussed in greater detail later in this chapter.[1]

Fibrinolysis

⑤ When primary PCI for patients with STEMI is not possible within a timely fashion, pharmacological reperfusion, or fibrinolysis, is an alternative to primary PCI. The available fibrinolytic agents are plasminogen activators that increase the conversion of plasminogen to plasmin. Plasmin binds to the fibrin strands within the thrombus, breaking them down and allowing blood flow to be restored.

Fibrinolysis is an important means of reperfusion and prevents 30 early deaths per 1,000 patients treated within 6 hours of symptom onset.[54] The mortality advantage of primary PCI over fibrinolysis in patients with STEMI is lost when primary PCI is delayed more than 120 minutes.[48] Therefore, guidelines recommend fibrinolysis when primary PCI cannot be performed within 120 minutes.[1] Situations where this may apply include when patients have immediate contraindications to receiving contrast dye, facility to which patients present is unable to perform PCI and transfer time would exceed 120 minutes, or when patients present at off-peak hours when the catheterization laboratory cannot be adequately staffed within 120 minutes. Non-PCI-capable hospitals should aspire to transfer patients with STEMI to a PCI-capable hospital within 30 minutes of arrival (door-in-door-out goal).[1] Yet, when the anticipated time to PCI is expected to exceed 120 minutes, fibrinolytic therapy should be given within 30 minutes of hospital arrival provided no contraindications are present.[1] In fact, for patients with STEMI, the time from hospital presentation until the start of fibrinolytic therapy (door-to-needle time) is a quality performance measure of timely and effective care.[55] In a recent analysis evaluating the timeliness of reperfusion for patients with STEMI, the median door-to-needle time for patients treated with fibrinolytics was approximately 24 minutes with approximately 60% meeting the goal of less than 30 minutes.[56] A coordinated approach among EMS, ED, cardiology, and pharmacy personnel is needed in order to improve this further.

Indications and contraindications to fibrinolytic therapy are outlined in Table 34-3. Fibrinolytic therapy is associated with a slight but significant risk for stroke, largely attributed to intracranial hemorrhage (ICH), which occurs in 0.9% to 1.0% of patients.[57] Significant predictors for ICH include advanced age, lower total body weight, female sex, preexisting cerebrovascular disease, and systolic and diastolic HTN at time of presentation.[57]

TABLE 34-3

Indications and Contraindications to Fibrinolytic Therapy for STEMI

Indications	Absolute Contraindications	Relative Contraindications
• Symptoms of acute coronary syndrome with an onset within 12 hours of first medical contact • ST-segment elevation of 1 mm or greater in two contiguous leads or new left bundle branch block on a 12-lead ECG • Anticipated that primary PCI cannot be performed within 120 minutes of first medical contact	• Any prior hemorrhagic stroke • Ischemic stroke within 3 months (except in past 4.5 hours) • Intracranial neoplasm or arteriovenous malformation • Active internal bleeding • Aortic dissection • Considerable facial trauma or closed-head trauma in the past 3 months • Intracranial or intraspinal surgery within 2 months • Severe, uncontrolled hypertension (unresponsive to emergency therapy) • For streptokinase,[a] treatment within the previous 6 months (if considering streptokinase again)	• BP >180/110 mm Hg on presentation or history of chronic poorly controlled hypertension • History of ischemic stroke greater than 3 months before • Recent major surgery (less than 3 weeks before) • Traumatic or prolonged CPR (greater than 10 minutes) • Recent internal bleeding (within 2-4 weeks) • Active peptic ulcer • Noncompressible vascular punctures • Pregnancy • Known intracranial pathology (dementia) • Oral anticoagulant therapy

[a] Streptokinase is no longer marketed in the United States but is available in other countries.

BP, blood pressure; CPR, cardiopulmonary resuscitation.

Data from Reference [1].

Relative contraindications to fibrinolytic therapy should be mitigated where possible (eg, giving antihypertensive medications to reduce blood pressure to less than 185/110 mm Hg) to reduce the risk for major bleeding, including ICH, prior to administration. Patients at high risk for major bleeding (including a history of ICH) presenting with an absolute contraindication should not receive fibrinolytic therapy and should be transferred to a hospital capable of performing PCI. It is important to weigh the potentially life-saving effect against the life-threatening potential for an adverse event in those with contraindications to fibrinolytic therapy, taking into consideration alternative options such as delayed PCI. The mortality benefit of fibrinolysis is highest when administered early after symptom onset but is negligible if administered to patients with symptom durations exceeding 12 hours. The use of fibrinolytics between 12 and 24 hours after symptom onset should be limited to patients with clinical and/or electrocardiographic evidence of ongoing ischemia.[1] Noncerebral bleeding from fibrinolysis has been reported to be as high as 13%.[57]

When fibrinolytic therapy is indicated, a fibrin-specific agent (alteplase, reteplase, or tenecteplase) is recommended over a non-fibrin-specific agent (eg, streptokinase) because of greater reperfusion success and less systemic bleeding with fibrin-specific agents.[1] Any fibrin-specific agent is acceptable as no drug has demonstrated superiority over the others with regard to the mortality benefit.[58] However, there is a trend toward a lower risk of major bleeding with tenecteplase compared to other fibrin-specific agents.[58] Therefore, safety considerations along with ease of administration or formulary restrictions may dictate the institutional preference of one agent over another. All hospitals should have protocols addressing fibrinolysis eligibility, dosing, and monitoring. Dosing considerations for the use of fibrinolytics in STEMI are provided in Table 34-4.

TABLE 34-4

Fibrinolytic Therapy Dosing in Patients with STEMI

Drug	Dosing Considerations	Comments
Alteplase (tPA)	15 mg IVP over 1-2 minutes, then 0.75 mg/kg (maximum 50 mg) IV over 30 minutes, then 0.5 mg/kg (maximum 35 mg) IV over 60 minutes; total dose not to exceed 100 mg	"Accelerated" 90-minute weight-based infusion
Reteplase (rPA)	10 units IVP over 2 minutes × 2 doses given 30 minutes apart	Double bolus, separated by 30 minutes
Tenecteplase (TNK-tPA)	<60 kg: 30 mg IVP;	Single, weight-based (~0.5 mg/kg) bolus administered over 5 seconds[a]
	60-69 kg: 35 mg IVP;	
	70-79 kg: 40 mg IVP;	
	80-89 kg: 45 mg IVP;	
	>90 kg: 50 mg IVP	

[a] In patients 75 years or older, the dose may be reduced by 50% to decrease the risk of intracranial hemorrhage.[59]

IVP, intravenous push. Please refer to Tables 33-5 and 33-7 for appropriate adjunctive antiplatelet and anticoagulant therapy for patients with STEMI treated with fibrinolytics.

Data from Reference [1].

TABLE 34-5

Antiplatelet Drug Use and Dosing Across the Spectrum of ACS and Management Strategy

Drug	STEMI		NSTE-ACS	
	Primary PCI	Fibrinolytic Reperfusion	Early Invasive Strategy	Ischemia-Driven Strategy
Aspirin				
Loading dose	162-325 mg	162-325 mg	162-325 mg	162-325 mg
Maintenance dose	81 mg daily	81 mg daily	81 mg daily	81 mg daily
$P2Y_{12}$ inhibitors				
Clopidogrel				
Loading dose	600 mg	300 mg	600 mg	300 mg
		Age greater than		

		75 years: No loading dose given		
Maintenance dose	75 mg daily	75 mg daily	75 mg daily	75 mg daily
Prasugrel		No recommendation		No recommendation[a]
Loading dose	60 mg		60 mg	
Maintenance dose	10 mg daily		10 mg daily	
	Weight less than 60 kg: 5 mg daily		Weight less than 60 kg: 5 mg daily	
Ticagrelor		No recommendation		
Loading dose	180 mg		180 mg	180 mg
Maintenance dose	90 mg twice daily		90 mg twice daily	90 mg twice daily
Cangrelor	30 mcg/kg IV bolus, followed by 4 mcg/kg/min IV infusion for at least 2 hours or duration of PCI	No recommendation	30 mcg/kg IV bolus, followed by 4 mcg/kg/min IV infusion for at least 2 hours or duration of PCI	No recommendation
GP IIb/IIIa inhibitor				
Eptifibatide	180 mcg/kg IV bolus × 2 given 10 minutes apart, followed by 2 mcg/kg/min IV infusion started after first bolus and continued for 18-24 hours after PCI	No recommendation	180 mcg/kg IV bolus × 2 given 10 minutes apart, followed by 2 mcg/kg/min IV infusion started after first bolus and continued for 18-24 hours after PCI	No recommendation
	CrCl less than 50 mL/min (0.83 mL/s):		CrCl less than 50 mL/min (0.83 mL/s):	
	Reduce infusion by 50%		Reduce infusion by 50%	
	Hemodialysis: Avoid use		Hemodialysis: Avoid use	
Tirofiban	25 mcg/kg IV bolus, followed by 0.15 mcg/kg/min	No recommendation	25 mcg/kg IV bolus, followed by 0.15 mcg/kg/min	No recommendation
	CrCl less than 60 mL/min (1.0 mL/s):		CrCl less than 60 mL/min (1.0 mL/s):	
	Reduce infusion by 50%		Reduce infusion by 50%	

CrCl, creatinine clearance; IC, intracoronary; IV, intravenous.

[a] Not mentioned in the ACC/AHA guidelines, but evidence of noninferiority compared to clopidogrel exists. Prasugrel dosing was a 30 mg loading dose followed by 10 mg daily. Patients weighing less than 60 kg or age 75 years or more received a maintenance dose of 5 mg daily.

Data from References [1,2].

As with primary PCI, antiplatelet therapy and parenteral anticoagulation should be given concomitantly in patients treated with fibrinolytic therapy to improve vessel patency and to prevent reocclusion.[1] Adjunctive antiplatelet and anticoagulant therapies are discussed later in this chapter.

Despite data suggesting a benefit and the feasibility of pre-hospital fibrinolysis, the administration of fibrinolytic therapy by EMS personnel to patients during transport to the hospital is not routine practice in the United States. Early angiography after fibrinolytic therapy, a practice referred to as a pharmacoinvasive approach, may reduce cardiovascular events compared to patients transferred for immediate PCI, yet increased rates of ICH have been implicated with this approach.[46,59] Transfer to a PCI-capable facility for possible "rescue PCI" after fibrinolysis is appropriate for those who fail fibrinolytic therapy and those patients with acute, severe HF or cardiogenic shock.[1]

Treatment Strategies in NSTE-ACS

Early Invasive Approach

While patients presenting with STEMI benefit from immediate reperfusion of the infarct-related artery due to complete arterial occlusion, patients presenting with NSTE-ACS typically have a partially occluded coronary artery with some residual perfusion and, therefore, the need for and urgency to perform PCI is not as critical. With an early invasive approach, the patient has a diagnostic angiography performed early in the hospital course, typically within the first 24 hours, with the intent to perform revascularization if appropriate, depending on the coronary anatomy.[2] An early invasive strategy improves cardiovascular outcomes in patients presenting with NSTE-ACS with the greatest benefits achieved in those patients with the highest risk for MACE. Risk stratification is, therefore, essential in NSTE-ACS to determine which patients will derive the most benefit from an early invasive approach. The benefit of routine invasive therapy is superior to an ischemia-guided approach (a more conservative watch and wait approach) usually in patients with advanced age (older than age 70), previous MI or revascularization, ST-segment changes, HF (especially with left ventricular dysfunction), elevated cTn, DM, and in those with positive results from noninvasive stress tests. Practice guidelines recommend an early invasive strategy in those with an elevated risk for death or MI (eg, high-risk and select intermediate-risk patients [see Table 34-1]), those with refractory angina, acute HF, other symptoms of cardiogenic shock, or arrhythmias.[2,26,60]

Ischemia-Guided Approach ("Medical Management")

In contrast to an early invasive approach, a more conservative management strategy for those with the lowest risk is referred to as an ischemia-guided approach, or "medical management," where anti-ischemic, antiplatelet, and anticoagulant medications are administered and PCI is not initially planned. The patient is evaluated for signs and symptoms of recurrent ischemia or hemodynamic instability and taken for invasive coronary angiography and possible PCI only if recurrent symptoms develop or noninvasive diagnostic testing (eg, coronary computed tomography angiography, stress testing) suggest obstructive CAD. This strategy is appropriate for select low- and intermediate-risk patients, for those with serious comorbidities or contraindications to angiography/PCI (eg, renal failure), or when the risks of the procedure outweigh the benefits of revascularization.[2] The ischemia-driven approach is also preferred by guidelines for those with a low likelihood of ACS, in women without troponin elevation, and in those who do not consent for revascularization.[2]

Antithrombotic Therapy

Due to the role of thrombus formation in the setting of ACS, timely and appropriate antithrombotic therapy is an important component of optimal pharmacotherapy. Antithrombotic therapy consists of antiplatelet and anticoagulant therapy. While platelets dominate the pathophysiologic process in arterial thrombosis, the central role of thrombin in both platelet activation and coagulation makes both types of therapy necessary in the acute phase of treatment in a patient with ACS. After hospital discharge, most patients are typically continued on long-term antiplatelet therapy only, although evidence for use of long-term anticoagulant therapy after ACS is emerging for some high-risk groups.

One of the most challenging aspects of the use of antithrombotic therapy in patients with ACS is that not all agents have been studied across the spectrum of ACS and its different management strategies. While some agents may have data in the setting of NSTE-ACS, they may not have data in

STEMI. For patients with NSTE-ACS, data are different for patients being managed with an ischemia-driven approach compared to those receiving PCI.[2] Some agents may have data in the setting of primary PCI in STEMI, but not with the use of fibrinolytics in STEMI.[1] Lastly, agents may have data in these different settings, but the doses may differ depending on the diagnosis or management strategy. Therefore, clinicians must know the evidence on appropriate antithrombotic drug use, dose, and duration based on the patient's diagnosis and management strategy to optimize patient outcomes and prevent adverse events.

Antiplatelet Therapy

The use and dosing of antiplatelet therapies for the treatment of ACS are summarized in Table 34-5.

Aspirin

Aspirin, or acetylsalicylic acid, has been a standard part of the treatment for ACS for several decades. Aspirin provides its antiplatelet effect by acetylating a hydroxyl group of serine 530 on the cyclooxygenase (COX)-1 enzyme on platelets and thereby preventing the conversion of arachidonic acid into a number of prostaglandins, and eventually thromboxane A_2.[61] Thromboxane A_2 produces platelet activation as well as vasoconstriction. While unbound aspirin has a half-life of only about 15 to 20 minutes, the irreversible binding of aspirin to the platelet COX-1 enzyme inhibits thromboxane A_2–induced platelet activation for the life of the platelet (7-10 days).

⑥ Aspirin is recommended for all patients with ACS without contraindications, regardless of the type of ACS or the management strategy. The initial dose of aspirin should be 162 to 325 mg (non-enteric coated) given as soon as possible.[1,2] Typically, this is given as 2 to 4 "baby" aspirin (81 mg in the United States) to be chewed and swallowed. The process of chewing allows for faster dissolution time and platelet inhibition in less than 30 minutes compared to about 60 minutes when tablets are consumed whole.[61] Patients undergoing PCI for NSTE-ACS or STEMI already receiving chronic aspirin doses of 81 mg daily should be given an additional dose of 81 to 325 mg before the procedure.[1,2]

After the initial dose of aspirin, daily doses of aspirin should be 81 mg daily and continued indefinitely.[1,2] Higher daily maintenance doses of aspirin (300-325 mg) do not reduce CV death, MI, or stroke compared to lower daily maintenance doses (75-100 mg), but significantly increase the incidence of gastrointestinal (GI) bleeding.[62]

Contraindications to aspirin include hypersensitivity to aspirin and major GI intolerance. In these rare cases, clopidogrel with a loading dose followed by a maintenance dose should be used as an alternative.[1,2] While ticagrelor may also be considered, there are no direct comparative data to aspirin available. The main adverse effects of aspirin include dyspepsia and GI bleeding, which is an extension of its inhibition of prostaglandins responsible for GI protection.[61] The use of low-dose and/or enteric-coated aspirin can provide a reduction in these adverse effects. Aspirin with an antacid, known as "buffered aspirin," does not provide GI protection. Although most surgical procedures can be conducted with patients on aspirin, it should be discontinued approximately 5 days before the procedure if desired.

$P2Y_{12}$ Inhibitors

⑥ Aspirin is rarely used as the sole antiplatelet agent in patients with ACS and is typically combined with an oral $P2Y_{12}$ inhibitor as part of dual antiplatelet therapy (DAPT). There are three orally administered $P2Y_{12}$ inhibitors (clopidogrel, prasugrel, and ticagrelor) and one IV agent (cangrelor) available in the United States, and their pharmacology is summarized in Table 34-6. Clopidogrel and prasugrel both belong to the chemical class of thienopyridines that are prodrugs requiring hepatic activation. Both agents have a thiol ring that must be opened to expose the sulfur atom. This sulfur then interacts with the sulfur within the $P2Y_{12}$ receptor creating an irreversible disulfide bond. The binding of the thienopyridine agent to the receptor prevents the receptor's ability to be activated by adenosine diphosphate and subsequent platelet activation and aggregation.

TABLE 34-6

$P2Y_{12}$ Inhibitor Pharmacology Comparisons

Property	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Drug class	Thienopyridine	Thienopyridine	Cyclopentyltriazolopyrimidine	ATP analogue
Absorption	≥50%	80%	36%	100%
Tmax	2 hours	30 minutes	60 minutes	2 minutes
Onset of action	75 mg: 3-5 days			2 minutes
	300 mg: 6-8 hours	10 mg: 3 days	90 mg: 2-3 days	
	600 mg: 2-4 hours	60 mg: 30-60 minutes	180 mg: 60 minutes	
Metabolism	Hepatic	Hepatic	Hepatic	ATPases in vascular endothelium
(CYP isoenzymes)	(2C19, 3A4, 1A2, 2B6)	(2B6, 3A4, 2C9, 2C19)	(3A4, 2C9)	
Prodrug	Yes	Yes	No	No

ATP, adenosine triphosphate; CYP, cytochrome p450.

Data from References [61,63].

Ticagrelor and cangrelor are not thienopyridines, and therefore do not require hepatic activation to provide their antiplatelet effect. Cangrelor is an adenosine triphosphate analog and ticagrelor belongs to the chemical class of a cyclopentyltriazolopyrimidine that has structural components similar to adenosine triphosphate. While adenosine diphosphate is a known activator of platelets through the $P2Y_{12}$ receptor, adenosine triphosphate is a known inhibitor of this receptor. Ticagrelor and cangrelor do not form an irreversible bond with the $P2Y_{12}$ receptor as thienopyridines but instead, bind reversibly in a different location. With ticagrelor and cangrelor, adenosine diphosphate is allowed to bind to the $P2Y_{12}$ receptor, but the signal is blocked and does not lead to platelet activation and aggregation. Hence, ticagrelor and cangrelor are $P2Y_{12}$ receptor inhibitors, just by a different mechanism than thienopyridines. Because they reversibly bind to the $P2Y_{12}$ receptor, more frequent dosing of ticagrelor (twice-daily dosing) and cangrelor (continuous infusion) is required.

⑥ Bleeding risk in patients treated with $P2Y_{12}$ inhibitors undergoing major surgery is of concern. In patients with ACS treated with a clopidogrel-based DAPT regimen, the risk of CABG-related major bleeding was approximately 50% higher in clopidogrel-treated patients when surgery was performed within 5 days of clopidogrel cessation compared to patients treated with aspirin alone.[64] The risk of CABG-related major bleeding in ACS patients treated with DAPT is more than four times higher with prasugrel than clopidogrel.[65] Consequently, clopidogrel and ticagrelor should be held for at least 5 days and prasugrel should be held for 7 days prior to elective surgery (eg, CABG surgery).[1,2] Because of its short duration of action, cangrelor can be continued until just a few hours before surgery, which is a favorable property of this agent.[63] Given the known bleeding risk associated with $P2Y_{12}$ inhibitor use and CABG, preloading patients with NSTE-ACS with a $P2Y_{12}$ inhibitor prior to PCI is controversial given that some may require CABG surgery. Administration of an oral $P2Y_{12}$ inhibitor prior to PCI does not offer a reduction in thrombotic outcomes compared to administration immediately following PCI.[66,67] It would still be prudent to preload the oral $P2Y_{12}$ inhibitor in patients with STEMI undergoing primary PCI, especially since CABG surgery is uncommon in these patients.

Clopidogrel

Conversion of clopidogrel to its active compound takes two cytochrome P450 (CYP) enzyme steps.[61] While multiple CYP enzymes take part in this conversion, CYP2C19 is responsible for at least 50% of this conversion. Patients with loss of function alleles (*2 or *3) have demonstrated a reduced ability to convert clopidogrel to its active form and have less platelet inhibition compared to patients with wild-type CYP2C19 (*1). It has also been demonstrated that up to 40% of patients receiving clopidogrel fail to achieve an optimal antiplatelet effect.[68] While there is a fair amount of variability in how the antiplatelet effect is determined, patients who fail to respond adequately to clopidogrel have a greater risk for MACE compared to patients with an adequate antiplatelet response. Clopidogrel is less effective than prasugrel or ticagrelor in patients with loss-of-function alleles, but has comparable efficacy to other oral $P2Y_{12}$ inhibitors in patients wild-type CYP2C19.[1,2,69,70] Although genetic polymorphisms of CYP2C19 contribute to the inadequate response to clopidogrel, CYP2C19 status only explains 12% to 15% of the variability demonstrated with clopidogrel.[68] Consequentially, lack of response to clopidogrel is multifaceted and can occur in patients with wild-type CYP2C19. Patients treated for ACS in whom de-escalation of DAPT is being considered (discussed below), platelet function testing to screen for high platelet reactivity may be considered 1 week after switching to clopidogrel in special circumstances (bleeding event, high bleeding risk, financial barriers).[70] Since proton pump inhibitors are known inhibitors of CYP2C19, concern has been raised about an increased risk for MACE in patients receiving these agents with clopidogrel. While the clopidogrel labeling information lists omeprazole and esomeprazole as being contraindicated, clinical evidence supporting this interaction is inconsistent.[68]

Clopidogrel has been extensively evaluated in patients with ACS. The CURE trial (Clopidogrel in Unstable Angina to Prevent Recurrent Events) compared aspirin alone to clopidogrel given as a 300 mg loading dose, followed by 75 mg daily for up to 12 months.[64] Patients receiving DAPT demonstrated a significant reduction in CV death, MI, and stroke compared to aspirin alone. This trial not only demonstrated the efficacy of clopidogrel but also established DAPT as the standard of care for patients presenting with ACS. Since 80% of the patients in this trial were medically managed, this dosing regimen is used in patients undergoing an ischemia-driven approach for NSTE-ACS.

A 600-mg loading dose provides a more potent and faster onset of antiplatelet activity and has demonstrated better efficacy in patients undergoing PCI compared to initially receiving a 300-mg loading dose of clopidogrel.[62] Patients who received an ischemia-driven approach did best with a 300-mg loading dose as in the CURE trial in regards to efficacy and safety outcomes. These data support the 600-mg clopidogrel loading dose in patients undergoing PCI for NSTE-ACS and STEMI.

Finally, clopidogrel is the only $P2Y_{12}$ inhibitor to be evaluated in large clinical trials in patients with STEMI receiving reperfusion with fibrinolytic therapy. Two trials have demonstrated the efficacy and safety of clopidogrel as part of DAPT in these patients.[71,72] Due to the increased concern of ICH in patients receiving fibrinolytics, only a 300 mg loading dose is used except for patients aged 75 or older who should not receive any loading dose.

Prasugrel

Prasugrel must also be converted to an active compound through hepatic conversion, but the conversion of prasugrel is more efficient, requiring a single CYP enzyme step, and multiple enzymes are capable of making the conversion.[19] Consequentially, the ability of prasugrel to be converted to its active compound is not limited and leads to faster and more potent platelet inhibition compared to clopidogrel. In patients undergoing PCI for NSTE-ACS or STEMI, prasugrel (as part of DAPT with aspirin) provided a significant reduction in CV death, MI, or stroke compared to clopidogrel.[65] The benefit of prasugrel was similar in the first few days of therapy, and after the first few days out to 1 year. Therefore, the reduction in MACE was due to not only more potent early antiplatelet therapy but also sustained potent antiplatelet therapy.

⑥ Greater efficacy, however, came at a cost of more non-CABG major bleeding and fatal bleeding. Upon further evaluation of the net clinical benefit (CV death, MI, stroke, and major bleeding), patients entering the trial with a history of stroke or transient ischemic attack were at greater risk for harm from prasugrel.[65] Therefore, these patients have an absolute contraindication to receiving prasugrel. Patients over the age of 75 years and those weighing less than 60 kg also had more bleeding with prasugrel compared to clopidogrel, but the overall net clinical benefit was neutral. Prasugrel should generally be avoided in patients over the age of 75 years. Exceptions may be made for patients who present with prior MI or DM, as the benefit in these patients outweighed the harm. Finally, in patients weighing less than 60 kg, the 60 mg loading dose of prasugrel is still given, but a 5 mg maintenance dose is recommended instead of the typical 10 mg dose although the safety and efficacy of this dose have not been established.

Prasugrel has been compared to clopidogrel in patients undergoing an ischemia-driven approach.[73] Although there was no increased risk of bleeding with prasugrel in this trial, there was also no difference in efficacy. The use of prasugrel in these patients is not mentioned in the current guidelines.[2] Prasugrel has also not been evaluated in patients with STEMI receiving reperfusion therapy with fibrinolytics.

Ticagrelor

⑥ As with prasugrel, ticagrelor provides faster and more potent inhibition of platelets compared to clopidogrel.[74] Although ticagrelor does not require hepatic activation, it is metabolized by CYP3A4. Therefore, ticagrelor is contraindicated in patients receiving strong CYP3A4 inhibitors such as azole antifungals and protease inhibitors, as well as strong inducers of this enzyme such as carbamazepine, phenytoin, rifamycins, and St. John's Wort. Patients on ticagrelor should not receive doses of simvastatin or lovastatin higher than 40 mg daily. Due to competition for P-glycoprotein, ticagrelor can increase digoxin concentrations by 30% to 50%.

Ticagrelor has been compared to clopidogrel as part of DAPT with aspirin in patients undergoing PCI (NSTE-ACS or STEMI) or undergoing an ischemia-driven approach for NSTE-ACS in a large clinical trial.[75] Patients receiving ticagrelor had a significant reduction in CV death, MI, or stroke compared to clopidogrel. While this reduction was evident within the first 30 days of therapy, two-thirds of the benefit was after the first 30 days out to 1 year. As with prasugrel, the benefit of ticagrelor was not simply due to more potent antiplatelet therapy early but also sustained potent antiplatelet therapy. The magnitude of benefit was similar in patients receiving an ischemia-driven approach to those receiving PCI. There was also a significant 21% reduction in CV mortality with the use of ticagrelor over clopidogrel, which has not been seen in other trials of $P2Y_{12}$ inhibitors. In the trial, higher doses of aspirin attenuated the benefit of ticagrelor compared to clopidogrel; only patients receiving low-dose aspirin (daily dose of 100 mg or less) received a benefit.[76] Based on these data, ticagrelor is contraindicated in patients receiving chronic aspirin daily doses of more than 100 mg. The mechanism of this interaction remains unknown. Although non-CABG major bleeding was significantly increased, there was no increase in fatal bleeding. Due to the increased risk of bleeding in older patients, clopidogrel may be a safer option based on data from trials evaluating patients aged 70 or 80 years or older.[77,78]

Ticagrelor has been compared to prasugrel as part of DAPT with aspirin in patients with ACS (NSTE-ACS or STEMI) for whom an early invasive treatment strategy was planned.[79] Prasugrel-treated patients had significantly lower rates of death, MI, or stroke compared to ticagrelor with similar rates of major bleeding. While ticagrelor is noninferior to clopidogrel for major bleeding risk in patients with STEMI receiving reperfusion with fibrinolytics, clopidogrel is the only $P2Y_{12}$ inhibitor with specific recommendations as an adjunct to fibrinolytic therapy in patients with STEMI.[80]

While all antiplatelet agents have the adverse effect of bleeding, the unique structure of ticagrelor produces additional adverse effects. Ticagrelor can interfere with adenosine degradation and increase adenosine concentrations via inhibition of adenosine uptake by erythrocytes.[1,74] This interaction most likely occurs through inhibition of the sodium-independent equilibrative nucleoside transporter (ENT)-1. Erythrocyte ENT-1 is responsible for the uptake of adenosine into the cell where it is metabolized by multiple mechanisms. The ability of ticagrelor to inhibit adenosine's uptake via ENT-1 is likely due to the adenosine core of the ticagrelor chemical structure.[74,77] This interaction produces an increase in adenosine exposure that likely explains these unique adverse effects. Significantly more patients receiving ticagrelor complained of dyspnea (13.8%) compared to those receiving clopidogrel (7.8%).[75] Symptoms of dyspnea are typically mild to moderate, require no specific therapy or workup, and usually dissipate within 2 to 4 weeks. Coaching of the patient through these episodes is often successful as ticagrelor was discontinued due to dyspnea in less than 1% of patients in the clinical trial. The use of ticagrelor has also been associated with an increase in asymptomatic ventricular pauses, increases in uric acid, and small increases in serum creatinine.[1,74]

Cangrelor

Cangrelor is the only available intravenously administered P2Y$_{12}$ inhibitor. Similar to ticagrelor, cangrelor is a reversible inhibitor of the P2Y$_{12}$ receptor and binds to the receptor at a different location than adenosine diphosphate. Despite the recommended loading doses, oral P2Y$_{12}$ inhibitors take a minimum of 1 to 2 hours to obtain maximum platelet inhibition and 3 to 7 days for platelet recovery after discontinuation.[63] Cangrelor achieves maximum platelet inhibition within approximately 2 minutes of an IV bolus dose, with the restoration of normal platelet reactivity within 1 to 2 hours of cessation of the infusion.[63] Cangrelor has an elimination half-life of less than 9 minutes and is metabolized by ATPases in the blood. Therefore, hepatic or renal dysfunction is not likely to impact the pharmacokinetics of cangrelor.[63] The fast return to normal platelet function may provide safety advantages for cangrelor over other P2Y$_{12}$ inhibitors in the context of bleeding or transition to CABG surgery.

The use of cangrelor in patients with ACS is not well defined. In a clinical trial evaluating the efficacy and safety of cangrelor for patients undergoing PCI (44% of whom had ACS), cangrelor provided a significant reduction in MACE with an increase in minor bleeding, but not major bleeding.[81] When used in this setting, cangrelor (bolus dose followed by an infusion) should be initiated before PCI. After PCI, an oral P2Y12 inhibitor (loading dose followed by maintenance dose) should be initiated; the overall duration of cangrelor infusion should be at least 2 hours. Since the chemical structure is similar to ticagrelor, dyspnea may occur with the use of cangrelor, but the shorter drug exposure time likely contributes to a lower incidence (1.2%) and discontinuation rate (0.1%) compared to ticagrelor (13.8% and 0.9%, respectively).[81,82]

Cangrelor may interfere with the binding of the active metabolites of clopidogrel and prasugrel. When clopidogrel is given with cangrelor, the ability of the thienopyridines to irreversibly inhibit platelet function was reduced.[82,83] Cangrelor directly prevents binding of the short-lived but irreversible active metabolite of clopidogrel. Once the infusion is discontinued, no impact on the pharmacodynamic effect of clopidogrel was seen. This same interaction would be expected with prasugrel. Therefore, if cangrelor is used, the loading dose of the thienopyridine should not be given until the cangrelor infusion has been discontinued. This interaction does not exist with ticagrelor.

Switching Antiplatelet Agents

Situations may occur after initial DAPT is chosen whereby therapy needs to change based upon some unique clinical scenario. Switching of therapy can be described as an escalation of therapy whereby clopidogrel is switched to a more potent P2Y$_{12}$ inhibitor such as ticagrelor or prasugrel. Reasons for escalation include cases of heightened risk for a coronary event or stent thrombosis, development of drug interaction, intolerance or nonadherence, identification of a genetic polymorphism to clopidogrel, or confirmation of inadequate platelet inhibition. In contrast, de-escalation typically refers to switching from a more potent P2Y$_{12}$ inhibitor to clopidogrel. Need for a de-escalation of P2Y$_{12}$ inhibitor therapy may be needed in response to bleeding, when there is a new indication to concurrently use an oral anticoagulant, or in cases when the cost is limiting medication access or leading to suboptimal adherence. Data on switching antiplatelet therapies is limited and is primarily based on pharmacodynamic studies. The efficacy and safety of switching agents during the first 12 months following ACS, therefore, is not fully known. But clinical decisions based on the reason for switching (ie, escalation versus de-escalation) and the timing from index event (ie, acute/early phase within the first 30 days versus later) must be weighed. One international consensus panel recommends that no loading dose be given when de-escalating therapy due to bleeding.[84] Loading doses are generally not needed when de-escalating therapy except when being when switching from ticagrelor to another P2Y$_{12}$ inhibitor.[84] Any escalation in therapy should be accompanied by a loading dose of the new agent regardless of the time of last P2Y$_{12}$ inhibitor dose, followed by maintenance therapy 24 hours after the last P2Y$_{12}$ inhibitor dose.[84] Finally, when switching between P2Y$_{12}$ inhibitors within 30 days of the index event, loading doses are recommended in most cases, except when the reason for switching is because of bleeding.[84] In general, the switch should occur 24 hours after the last dose of previous P2Y$_{12}$ inhibitor.[84]

Glycoprotein IIb/IIIa Inhibitors

The binding of fibrinogen to activated GP IIb/IIIa receptors represents the final step in platelet aggregation, making inhibition of this receptor an ideal target in patients with ACS. Each of the agents is only available as an IV infusion.

Eptifibatide and tirofiban are peptide and nonpeptide inhibitors of the GP IIb/IIIa receptor, respectively. These agents have a reversible binding of the

GP IIb/IIIa receptor. Therefore, platelet function recovery occurs in 2 to 4 hours after discontinuation of the infusion. The reversible binding of these agents requires that they overwhelm the ability of fibrinogen to bind to the GP IIb/IIIa receptor with high concentrations. Consequently, platelet transfusion would not be able to absorb the excess drug and would not be helpful in the management of bleeding with eptifibatide or tirofiban.

Besides bleeding, GP IIb/IIIa inhibitors can also cause significant thrombocytopenia in about 0.5% of patients.[19] Given that GP IIb/IIIa inhibitors should be administered with a heparin, it is important to differentiate GP IIb/IIIa inhibitor-induced thrombocytopenia from heparin-induced thrombocytopenia (HIT).[85] Thrombocytopenia from a GP IIb/IIIa inhibitor occurs more rapidly (within hours) and the platelet count nadir is typically lower (about 20,000/μL [20×10^9/L]) compared to HIT. While the efficacy of platelet transfusion for thrombocytopenia from eptifibatide or tirofiban is limited, it would unlikely be harmful as in HIT.[85]

Although GP IIb/IIIa inhibitors significantly reduce MACE, the majority of trials were conducted before DAPT became standard-of-care and before the more potent $P2Y_{12}$ inhibitors prasugrel and ticagrelor were available. In a study comparing the combination of a GP IIb/IIIa inhibitor and unfractionated heparin to unfractionated heparin alone in patients with NSTE-ACS receiving PCI and a 600 mg loading dose of clopidogrel, patients treated with the GP IIb/IIIa inhibitor had a significant reduction in MACE but the benefit was only in patients who had an elevated cTn.[86] Therefore, GP IIb/IIIa inhibitors provide added benefit in the setting of early DAPT but should be reserved for high-risk patients with elevated cTn. The ability of GP IIb/IIIa inhibitors to reduce MACE in patients receiving prasugrel or ticagrelor remains unknown. In trials comparing a strategy of GP IIb/IIIa inhibitors plus unfractionated heparin to bivalirudin alone in patients with ACS undergoing PCI, no differences in MACE were observed, but there was significantly less major bleeding with bivalirudin alone.[87,88] While these trials have many limitations, clinicians have consistently used less GP IIb/IIIa inhibitors over the last decade.

Patients with NSTE-ACS undergoing an ischemia-driven approach do not derive benefit from GP IIb/IIIa inhibitors and should not be used in these patients.[2] Patients with STEMI receiving reperfusion with fibrinolytics have significant increases in major bleeding and ICH when GP IIb/IIIa inhibitors are used concomitantly and they should be avoided in these patients as well.[1]

⑥ While the use of GP IIb/IIIa inhibitors has been diminishing over the years, the patient for whom GP IIb/IIIa inhibitors may provide the most benefit is one receiving PCI for NSTE-ACS with elevated cTn, (eg, suffering MI) or STEMI who has not been preloaded with a $P2Y_{12}$ inhibitor and is not being treated with bivalirudin. Guidelines also state that it is reasonable to use a GP IIb/IIIa inhibitor in patients who are preloaded with clopidogrel.[1,2,60,86] In this setting, consensus guidelines recommend the use of an 18 to 24-hour infusion (eptifibatide and tirofiban) but the contemporary use of these drugs continues to evolve. These agents should always be given concurrently with unfractionated heparin or a low-molecular-weight heparin (LMWH) but the anticoagulant should be discontinued immediately following the PCI procedure to reduce the risk of major bleeding.

Anticoagulants

Although patients with ACS are typically treated with two antiplatelet agents for at least a year, usually a single anticoagulant is used in these patients and the duration is abbreviated (typically the initial few days of hospitalization).[1,2] Currently available anticoagulants inhibit the production of thrombin by inhibiting factor Xa, inhibiting thrombin itself, or a combination of these. While the use of oral anticoagulants may be common for other thromboembolic disease states, all of the current evidence in the acute management of ACS is with injectable agents. The use and dosing of anticoagulant therapies for the treatment of ACS are summarized in Table 34-7.

TABLE 34-7

Anticoagulant Drug Use and Dosing Across the Spectrum of ACS and Management Strategy

Drug	STEMI		NSTE-ACS	
	Primary PCI	Fibrinolytic reperfusion	Early invasive strategy	Ischemia-driven strategy
Bivalirudin	0.75 mg/kg IV bolus, followed	No recommendation	0.10 mg/kg IV bolus, followed by 0.25 mg/kg/hr IV infusion	No recommendation

	by 1.75 mg/kg/hr IV infusion until completion of PCI CrCl less than 30 mL/min (0.5 mL/s): Reduce infusion to 1 mg/kg/hr		continued until completion of PCI	
Enoxaparin	0.5 mg/kg one time IV bolus[a]	30 mg IV bolus, followed by 1 mg/kg SC every 12 hours for up to 8 days or hospital discharge SC doses should be initiated within 15 minutes of the IV bolus. The first two SC doses should be capped at 100 mg CrCl less than 30 mL/min (0.5 mL/s): 30 mg IV bolus, followed by 1 mg/kg SC every 24 hours. The first SC dose should be capped at 100 mg Age 75 years or more: No IV bolus. Initiate at 0.75 mg/kg SC every 12 hours The first two SC doses should be capped at 75 mg CrCl less than 30 mL/min (0.5 mL/s) AND age 75 years or more: No IV bolus. Initiate at 1 mg/kg every 24 hours The first dose should be capped at 100 mg	1 mg/kg SC every 12 hours until PCI A 0.3 mg/kg IV bolus should be given if PCI occurs before two SC doses have been given, or if the last dose was given 8 hours or more prior to PCI CrCl less than 30 mL/min (0.5 mL/s): 1 mg/kg SC every 24 hours An initial 30 mg IV bolus can be given	1 mg/kg SC every 12 hours for the duration of hospitalization An initial 30 mg IV bolus can be given CrCl less than 30 mL/min (0.5 mL/s): 1 mg/kg SC every 24 hours
Fondaparinux	No recommendation	2.5 mg IV first dose, followed by 2.5 mg SC daily for up to 8 days or hospital discharge	2.5 mg SC daily until PCI At the time of PCI: No GP IIb/IIIa: IV UFH 85 units/kg[b] With GP IIb/IIIa: IV UFH 60 units/kg[b]	2.5 mg SC daily for up to 8 days or duration of hospitalization
Unfractionated heparin	No GP IIb/IIIa: 70-100 units/kg IV	60 units/kg (maximum initial bolus: 4,000 units) IV	60 units/kg (maximum initial bolus: 4,000 units) IV bolus,	60 units/kg (maximum initial bolus: 4,000 units) IV

	bolus to achieve a therapeutic ACT[b] GP IIb/IIIa: 50-70 units/kg IV bolus to achieve a therapeutic ACT[b]	bolus, followed by 12 units/kg/hr (maximum initial infusion rate: 1,000 units/hr)	followed by 12 units/kg/hr (maximum initial infusion rate: 1,000 units/hr)[b]	bolus, followed by 12 units/kg/hr (maximum initial infusion rate: 1,000 units/hr)

[a] Not mentioned in the ACC/AHA guidelines, but evidence exists

[b] Additional IV boluses of unfractionated heparin may be needed to maintain a therapeutic ACT

ACT, activated clotting time; CrCl, creatinine clearance; IV, intravenous; SC, subcutaneous; UFH, unfractionated heparin.

Data from References [1,2].

Unfractionated Heparin

Unfractionated heparin has been widely used in the management of patients with ACS for several decades. The unfractionated heparin molecule is a highly sulfated polysaccharide. Unfractionated heparin provides its anticoagulant activity by binding to the endogenous anticoagulant antithrombin (AT) via a unique pentasaccharide sequence, substantially increasing its affinity for clotting factor inhibition.[89] These unfractionated heparin–AT complexes can then inhibit clotting factors IXa, Xa, XIa, XIIa, and thrombin, with most of the impact provided through inhibition of factor Xa and thrombin. Inhibition of thrombin requires a tertiary binding between the unfractionated heparin–AT and thrombin molecules. This requires that the chain length of the inhibitory molecule be at least 18 saccharides long.[89] This additional binding is not necessary for inhibition of factor Xa. Since most unfractionated heparin molecules are approximately 45 to 50 saccharides long, unfractionated heparins can inhibit factor Xa and thrombin in an equal 1:1 ratio.[89]

The anticoagulant effect of unfractionated heparin has significant interpatient variability.[89] This is due to the additional binding of unfractionated heparin with endothelial cells, plasma protein, and ingestion by macrophages. As a result of the unpredictable anticoagulant response of unfractionated heparin, therapy needs to be monitored with an activated partial thromboplastin time (aPTT). The aPTT should be measured every 6 hours until two consecutive readings are within the therapeutic range, as determined by the individual institutional protocols, then every 24 hours for the duration of unfractionated heparin therapy. Although goal ranges for aPTT vary by institution based on the assays used, an aPTT goal of 1.5 to 2 times the institution's control value is recommended.[1] If a dose adjustment is made, the same monitoring schedule should be restarted. While some institutions have adopted the use of anti-Xa levels instead of aPTT to monitor heparin therapy, guideline recommendations are specific to aPTT. Due to the short duration of anticoagulant therapy in patients with ACS, it is not uncommon for the unfractionated heparin to be discontinued before the patient ever achieves two consecutive therapeutic aPTT measurements. Platelet counts should also be monitored daily or every other day to monitor for HIT. While HIT typically presents 5 days or more after unfractionated heparin exposure, it can occur within hours if the patient has been exposed to heparin in the last 3 months.[85] If HIT is suspected, unfractionated heparin should be discontinued and anticoagulation with an IV direct thrombin inhibitor should be provided.

⑦ Based on experience, unfractionated heparin can be used across the spectrum of ACS, and regardless of the management strategy.[1,2] The recommended dosing of unfractionated heparin has changed several times over the past decades in an attempt to maximize efficacy and minimize bleeding. The recommended dose of unfractionated heparin is an IV bolus of 60 units/kg (initial maximum total dose of 4,000 units) and an initial infusion rate of 12 units/kg/hr (initial maximum 1,000 units/hr). This is the recommended dose regardless of the ACS diagnosis or management strategy.[1,2] After initiation of heparin, dosage adjustments can exceed the recommended maximums as necessary to achieve the aPTT goal. Bolus doses of 2,000 to 5,000 units can also be given in the cardiac catheterization laboratory at the time of PCI to maintain an adequate activated clotting time (ACT). In a meta-analysis comparing the use of heparin plus aspirin to aspirin alone in patients with NSTE-ACS, the risk of death or MI was reduced by 33% in heparin-treated patients.[90] Because of the long-standing experience and use of unfractionated heparin in patients with ACS, it is the standard-of-care comparison in clinical trials.

Low-Molecular-Weight Heparins

Similar to unfractionated heparin, LMWHs must first bind to AT to provide their anticoagulant activity. LMWHs are created through chemical or enzymatic depolymerization of unfractionated heparin molecules.[89] This creates a mixture of lower molecular weight fragments compared to the larger intact unfractionated heparin molecule. Most of these fragments are less than 18 saccharides long. Consequently, LMWH's anticoagulants primarily inhibit factor Xa due to the fewer number of larger fragments able to inhibit thrombin. The ratio of factor Xa to thrombin inhibition for an LMWH is typically 3:1 or 4:1, depending on the process of depolymerization.[89]

Compared to unfractionated heparins, LMWHs provide a predicable anticoagulant dose-response with no need for routine therapeutic monitoring. While most patients receiving an LMWH do not require therapeutic monitoring, an anti-Xa level may be desired in certain patient populations.[89] Patient groups where anti-Xa monitoring may be helpful would be pediatrics, pregnancy, obesity (greater than 190 kg), and patients with severe renal insufficiency (eg, creatinine clearance [CrCl] less than 30 mL/min [0.5 mL/s]). While pediatric and pregnant patients rarely have ACS, obesity and severe renal insufficiency are more common in patients with ACS. The target peak anti-Xa level is 0.3 to 0.7 IU/mL (kIU/L) drawn 4 hours after the third dose. Since patients with ACS typically receive anticoagulant therapy for only a few days, the utility of anti-Xa monitoring in these patients is limited. There is also a lower incidence of HIT with the use of LMWHs (less than 2%) compared to unfractionated heparin (2%-5%).[85] Even though the risk of HIT is lower with LMWH, the monitoring of platelet counts is still warranted. Due to the 90% cross-reactivity between HIT antibodies from LMWH and unfractionated heparin, LMWH is not considered a safe alternative in patients who develop HIT from unfractionated heparin and vice versa.[85]

While other LMWHs are available, enoxaparin is the most widely studied agent in patients with ACS and is the only LMWH recommended in the ACC/AHA guidelines.[1,2] Data supporting the use of enoxaparin exist in patients with NSTE-ACS and STEMI regardless of the management or reperfusion strategy used. Unfortunately, the dosing of enoxaparin varies across these different settings, requiring careful attention to assure the right dose is used in the right patient to maximize efficacy and safety (Table 34-7).

⑦ In patients with NSTE-ACS undergoing an ischemia-driven approach, the use of subcutaneous (SC) enoxaparin at 1 mg/kg every 12 hours for up to 3 days, when compared to IV unfractionated heparin, significantly reduces the risk of MACE without increasing major bleeding.[91] In patients with NSTE-ACS treated with an early invasive strategy, SC enoxaparin (1 mg/kg every 12 hours) has similar efficacy but more major bleeding compared to unfractionated heparin.[92] This trial was complicated by a large number of patients receiving both anticoagulants during the trial. Interestingly, in patients who were treated with either enoxaparin or IV unfractionated heparin alone, those randomized to enoxaparin had a 17% reduction in the risk of death or MI at 30 days and at 6 months without a significant increase in major bleeding compared to IV unfractionated heparin. Based on these data, either unfractionated heparin or enoxaparin is recommended in patients with NSTE-ACS. Patients who have received less than two SC doses prior to PCI should receive a supplemental IV enoxaparin bolus dose of 0.3 mg/kg to provide sufficient anticoagulation during the procedure.[2] Patients who have received at least two SC doses and arrive at PCI within 8 hours of their last dose do not require any additional anticoagulation for PCI.[2,92] Patients having PCI performed within 8 to 12 hours of their last dose should also receive the supplemental IV enoxaparin bolus dose.[2,92] Patients with a CrCl less than 30 mL/min (0.5 mL/s) should receive enoxaparin 1 mg/kg every 24 hours instead of every 12 hours.

⑦ In patients with STEMI receiving reperfusion with fibrinolytics, enoxaparin significantly reduced death and MI when compared to unfractionated heparin.[93] Major bleeding was increased, but there was no increase in ICH which occurred in less than 1% of patients. Dosing of enoxaparin in this trial used a 30 mg IV bolus followed immediately by 1 mg/kg SC every 12 hours. The bolus dose is necessary in the setting of STEMI due to the rapid need for reperfusion therapy. Patients aged 75 years or greater and those with a CrCl less than 30 mL/min (0.5 mL/s) need to receive altered dosing to reduce the risk of bleeding in these higher-risk patients (Table 34-7). Trials in patients receiving primary PCI for STEMI have used a single IV dose of 0.5 mg/kg of enoxaparin. In a meta-analysis of trials evaluating this dose of enoxaparin in primary PCI, there is a reduction in mortality and significantly less major bleeding compared to unfractionated heparin.[94] Despite these data, a definitive clinical trial has not been conducted with enoxaparin in this setting.

Fondaparinux

Fondaparinux is a synthetic molecule existing of only the five saccharides needed to bind to and potentiate the activity of AT.[89] While others have been investigated, fondaparinux is the only available pentasaccharide worldwide. Due to the small size of the molecule, once it binds to AT it can only inhibit factor Xa and has no activity against thrombin. Similar to LMWH, fondaparinux also provides a predictable anticoagulant dose-response and no need for therapeutic monitoring.[89] While case reports of fondaparinux-induced thrombocytopenia have been reported, the incidence is thought to be extremely rare.[85] Based on the lack of antibody cross-reactivity, it is reasonable to consider the use of fondaparinux in patients with a history of HIT.[85] Based on the long half-life of fondaparinux, the SC dose (2.5 mg) is only given once daily. Fondaparinux is contraindicated in patients with a CrCl of less than 30 mL/min (0.5 mL/s) due to the significant degree of renal elimination. There can also be accumulation in patients with a CrCl between 30 and 60 mL/min (0.5 and 1.0 mL/s), but this is typically not a factor with the short duration of therapy in patients with ACS.[95]

⑦ The use of fondaparinux in patients with ACS has been evaluated in two large trials.[96,97] The trial in NSTE-ACS evaluated patients receiving either an ischemia-driven or invasive management strategy and found similar efficacy between fondaparinux and enoxaparin, with significantly less major bleeding in patients receiving fondaparinux.[97] Although a number of issues in the trial may have explained the observed difference in bleeding, fondaparinux can be considered in patients undergoing an ischemia-driven approach who are at a high risk of bleeding.[2] Patients undergoing PCI experienced an increase in catheter-related thrombosis if they received fondaparinux compared to enoxaparin.[97] Due to this concern, supplemental doses of IV unfractionated heparin must be given if a patient receiving fondaparinux requires PCI.[2] Consequently, fondaparinux is rarely used and not recommended in the United States for patients with NSTE-ACS receiving an invasive management approach.[60]

⑦ The trial utilizing fondaparinux in STEMI evaluated patients receiving reperfusion with either fibrinolytics or primary PCI.[96] In this trial, fondaparinux was compared to unfractionated heparin. Similar to the NSTE-ACS trial, patients receiving primary PCI had significantly higher rates of catheter-related thrombosis if they received fondaparinux compared to unfractionated heparin.[1,96] As in NSTE-ACS, fondaparinux use has been constrained by this limitation and is not recommended in patients receiving primary PCI.[60] In patients receiving fibrinolytics, the use of fondaparinux has similar efficacy and safety compared to unfractionated heparin.[96] Based on the lack of benefit over unfractionated heparin, and the benefit with enoxaparin over unfractionated heparin in this population, fondaparinux is rarely used in patients with STEMI.

Bivalirudin

Bivalirudin is an intravenously administered direct thrombin inhibitor. Being a "direct" inhibitor means bivalirudin does not have to first bind to AT to provide its anticoagulant effect.[89] Because of the lack of AT binding, bivalirudin can inhibit not only free or soluble thrombin, similar to unfractionated heparin and LMWH but also fibrin-bound thrombin. Fibrin-bound thrombin is still enzymatically active, but the large AT–anticoagulant complexes are unable to gain access and, therefore, exert anticoagulant activity.[89] The clinical benefit of bivalirudin's inhibition of this larger pool of thrombin is difficult to quantify.

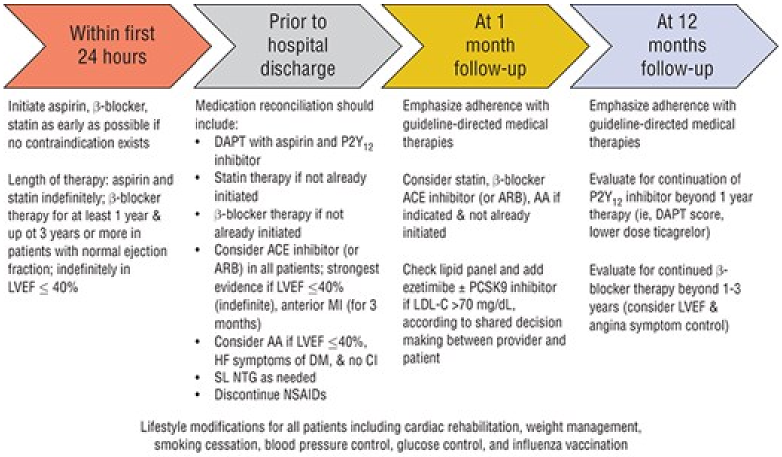
⑦ Bivalirudin has not been evaluated in patients with NSTE-ACS undergoing an ischemia-driven approach or in patients with STEMI receiving reperfusion with fibrinolytics. Therefore, bivalirudin is only used in patients with ACS who receive PCI and can be monitored with an ACT in the catheterization laboratory.[1,2,89] In one NSTE-ACS trial evaluating anticoagulation as part of an early invasive approach, patients received a heparin derivative (unfractionated heparin or enoxaparin) with a GP IIb/IIIa inhibitor, bivalirudin with a GP IIb/IIIa inhibitor, or bivalirudin alone.[87] There was no difference in efficacy or safety in patients receiving heparin or LMWH with a GP IIb/IIIa inhibitor compared to bivalirudin with a GPII/IIIa inhibitor. Consequently, because of the lack of benefit and increased cost associated with the combination of bivalirudin and a GP IIb/IIIa inhibitor, this regimen is not recommended in patients with NSTE-ACS undergoing PCI. Patients receiving bivalirudin alone had similar efficacy but significantly less major bleeding compared to heparin or LMWH with a GP IIb/IIIa inhibitor. The patients who were not preloaded with clopidogrel in the trial had significantly more MACE if they received bivalirudin alone.[2,87] Therefore, bivalirudin may not be as protective in patients who do not receive a $P2Y_{12}$ inhibitor prior to PCI. Similar to the study in NSTE-ACS, bivalirudin alone had similar efficacy with significantly less major bleeding compared to unfractionated heparin with a GP IIb/IIIa in patients undergoing primary PCI for STEMI.[88] These data led to a significant reduction in the use of GP IIb/IIIa inhibitors. Bivalirudin does not offer efficacy or safety benefit over unfractionated heparin alone in the setting of primary PCI for STEMI, particularly as vascular access to perform PCI has moved from a predominantly femoral arterial approach associated with higher rates of bleeding to a radial artery approach associated with less bleeding.[98–100] While the role of bivalirudin in these patients is recommended in the guidelines, many cardiologists have come full circle and often use unfractionated heparin for primary PCI for patients with STEMI instead of bivalirudin.

Secondary Prevention of Ischemic Events

For most patients, the initial 24 hours of ACS care are focused on reperfusion (if appropriate), antithrombotic therapy, and acute supportive measures. After a diagnosis of ACS, patients are considered to have atherosclerotic cardiovascular disease (ASCVD) and should be treated aggressively because they are at the highest risk of recurrent MACE. Secondary prevention strategies proved to accomplish these goals typically include anti-ischemic, antiplatelet, lipid-lowering, and antihypertensive therapies (Table 34-8).[1,2,29] Specific pharmacotherapy proved to decrease mortality, HF, reinfarction or stroke, and stent thrombosis should be initiated prior to hospital discharge in all patients without contraindications. Medication reconciliation at discharge should include assessment for DAPT, β-blocker, angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), and statin therapy unless a contraindication exists (Fig. 34-3). In addition, short-acting nitroglycerin should be prescribed as needed for any subsequent episode of acute angina for patients not taking phosphodiesterase-5 inhibitors. Select patients may also meet the criteria for aldosterone antagonist use.

FIGURE 34-3

Secondary prevention of ischemic events over time. (AA, aldosterone antagonist; CI, contraindications; DM, diabetes mellitus; LDL-C, low-density lipoprotein cholesterol (70 mg/dL is expressed in SI units as 1.81 mmol/L); NSAID, nonsteroidal anti-inflammatory drug; SL NTG, sublingual nitroglycerin)



Within first 24 hours

Initiate aspirin, β-blocker, statin as early as possible if no contraindication exists

Length of therapy: aspirin and statin indefinitely; β-blocker therapy for at least 1 year & up ot 3 years or more in patients with normal ejection fraction; indefinitely in LVEF ≤ 40%

Prior to hospital discharge

Medication reconciliation should include:

- DAPT with aspirin and $P2Y_{12}$ inhibitor
- Statin therapy if not already initiated
- β-blocker therapy if not already initiated
- Consider ACE inhibitor (or ARB) in all patients; strongest evidence if LVEF ≤40% (indefinite), anterior MI (for 3 months)
- Consider AA if LVEF ≤40%, HF symptoms of DM, & no CI
- SL NTG as needed
- Discontinue NSAIDs

At 1 month follow-up

Emphasize adherence with guideline-directed medical therapies

Consider statin, β-blocker ACE inhibitor (or ARB), AA if indicated & not already initiated

Check lipid panel and add ezetimibe ± PCSK9 inhibitor if LDL-C >70 mg/dL, according to shared decision making between provider and patient

At 12 months follow-up

Emphasize adherence with guideline-directed medical therapies

Evaluate for continuation of $P2Y_{12}$ inhibitor beyond 1 year therapy (ie, DAPT score, lower dose ticagrelor)

Evaluate for continued β-blocker therapy beyond 1-3 years (consider LVEF & angina symptom control)

Lifestyle modifications for all patients including cardiac rehabilitation, weight management, smoking cessation, blood pressure control, glucose control, and influenza vaccination

TABLE 34-8

Chronic Medications to Reduce Risk of MACE and Control Symptoms Following ACS

Drug	Indication in ACS Patients (Class of Recommendation)[a]	Contraindication/Caution	Dose (All doses are oral unless indicated)	Adverse Effects
Aspirin	All patients without contraindications	• Hypersensitivity to aspirin or NSAID • History of asthma, rhinitis, and nasal polyps • History of upper GI bleeding • Bleeding disorder/active	• 81 mg once daily	• Dyspepsia, GI bleeding

		bleeding		
$P2Y_{12}$ inhibitors	All patients without contraindications	- Thienopyridine hypersensitivity - Bleeding disorder/active bleeding - Previous intracranial hemorrhage - Prasugrel: prior TIA or stroke - Ticagrelor: aspirin doses greater than 100 mg daily; strong CYP3A4 inhibitors or inducers	- Clopidogrel 75 mg once daily - Prasugrel 10 mg once daily; weight less than 60 kg: 5 mg daily - Ticagrelor 90 mg twice daily	Bleeding, rash Ticagrelor: dyspnea, ventricular pauses, bradycardia
β-Blockers	All patients without contraindications	- Signs of heart failure - Low cardiac output state - High-grade AV block - Active asthma or reactive airway disease	- Carvedilol 6.25 mg twice daily; target dose (in patients with HFrEF): 25 mg twice daily as tolerated - Metoprolol 25-50 mg every 6-12 hours for 2-3 days, then once (metoprolol succinate) or twice daily (metoprolol tartrate); target dose (in patients with HFrEF): 200 mg daily - Continue therapy for at least 3 years, indefinitely in patients with concomitant HFrEF - Other β-blockers may be considered; in patients with HFrEF, use either metoprolol succinate, carvedilol, or bisoprolol	Hypotension, heart failure, bradycardia, cardiogenic shock, AV block, exacerbation of asthma or reactive airway disease
Statins	All patients without contraindications	- Active liver disease - Pregnancy - Breastfeeding - Concomitant use of fibrate	- Atorvastatin 80 mg daily - Rosuvastatin 20-40 mg daily	GI discomfort, arthralgia, myalgia, musculoskeletal pain, hepatotoxicit
Nonstatin therapies for cholesterol management	Patients with very high-risk ASCVD (eg, post-ACS) with LDL-C greater than 70 mg/dL (1.81 mmol/L) on maximally tolerated statin therapy	- Hypersensitivity - Simvastatin/ezetimibe: strong CYP3A4 inhibitors	- Ezetimibe 10 mg daily - Simvastatin 40 mg/ezetimibe 10 mg - Alirocumab 75 mg SC every 2 weeks or 300 mg SC every 4 weeks Evolocumab 140 mg SC	Ezetimibe and combination: GI discomfort, arthralgia, myalgia, musculoskeletal pain

			every 2 weeks or 420 mg SC monthly	Alirocumab: injection site pain, hypersensitiv
ACE inhibitors	All patients without contraindications	• Hypotension • Renal failure • Hyperkalemia	• Lisinopril 2.5-5 mg daily; target dose: 10-40 mg daily • Enalapril 2.5-5 mg twice daily; target dose: 10-20 mg twice daily Captopril 6.25-12.5 mg three times daily; target dose: 25-50 mg three times daily • Ramipril 2.5 mg twice daily; target dose: 5 mg twice daily • Trandolapril 0.5-1 mg daily; target dose: 4 mg daily	Hypotension, hyperuricemia, hyperkalemia, worsening renal function, chronic cough, angioedema
ARBs	Patients intolerant to ACE inhibitors	• Hypotension • Renal failure • Hyperkalemia	• Valsartan 20 mg twice daily; target dose: 160 mg twice daily	Hypotension, hyperuricemia, hyperkalemia, worsening renal function
Aldosterone antagonist	Patients with LVEF 40% (0.40) or less and either DM or symptoms of HF	• Elevated serum creatinine • Men: 2.5 mg/dL (221 μmol/L) or greater • Women: 2.0 mg/dL (177 μmol/L) or greater • CrCl 30 mL/min (0.5 mL/s) or less • Serum potassium 5.0 mEq/L (mmol/L) or greater	• Eplerenone 25 mg daily; target dose: 50 mg daily • Spironolactone 12.5-25 mg daily; target dose: 25-50 mg daily	Hyperkalemia, worsening renal function
Nitroglycerin	All patients without contraindications	• Hypotension • Avoid if recent PDE_5 inhibitor use • Avanafil: within 12 hours • Sildenafil: within 24 hours • Vardenafil: within 24 hours • Tadalafil: within 48 hours	• SL: 0.3-0.4 mg every 5 minutes, up to 3 doses PRN	Flushing, headache, hypotension, tachycardia

[a] AHA/ACC class of recommendations: I, benefit far outweighs the risk, treatment should be administered; IIb, the benefit is equal to or exceeds the risk, additional studies with broad objectives are needed, treatment may be considered.

AV, atrioventricular; CrCl, creatinine clearance; CYP3A4, cytochrome p450 isoenzyme 3A4; GI, gastrointestinal; HF, heart failure; NSAID, nonsteroidal anti-inflammatory drug; PDE5, phosphodiesterase-5; PRN, as needed; SC, subcutaneously; TIA, transient ischemic attack.

Data from References [1,2,101–103].

In addition to evaluating patients for the use of medications proved to reduce the risk of MACE or recurrent symptoms of angina, additional interventions may be appropriate to optimize outcomes and improve safety. Aggressive risk factor modification strategies such as increased physical activity, dietary modification, weight loss, blood pressure modification, and smoking cessation should be communicated to all patients, initiated, and continued indefinitely.[104] Proton pump inhibitors provide a protective benefit in patients at the highest risk for GI bleeding from DAPT and may be considered for select patients (eg, history of GI bleeding, triple therapy with DAPT, and an oral anticoagulant with or without a history of GI bleeding).[2] All patients should refrain from chronic use of nonsteroidal anti-inflammatory drugs with a high degree of cyclo-oxygenase-2 selectivity as they are associated with increased cerebrovascular and cardiovascular events.[1,2] Finally, for patients with cardiovascular disease, including those hospitalized for ACS, an annual influenza vaccination lowers the risk of MACE and is recommended as part of the care plan.[1,2,105,106]

Duration of Dual Antiplatelet Therapy (DAPT)

⑧ The ACC/AHA has published guidelines specifically related to dosing, initiation, and duration of DAPT after ACS, including situations when therapy should be discontinued.[1,2,107] In general, shorter durations of DAPT are appropriate for those patients with a lower ischemic risk who are at high-risk for bleeding. Conversely, longer durations of DAPT may be reasonable in patients at higher ischemic risk if bleeding risk is low. No randomized trials have compared different durations of DAPT specifically in the ACS setting. Yet, because the ischemic risk following ACS is considered high, DAPT with aspirin plus a $P2Y_{12}$ receptor inhibitor is indicated for most patients treated for ACS for a minimum of 12 months regardless of whether the patient was medically managed or if the patient undergoes some type of revascularization.[1,2,107] For patients with STEMI treated with fibrinolysis, the minimum recommended duration of DAPT is 14 days.[1,107] Every patient receiving DAPT should understand the benefit as well as risks associated with the therapy and the importance of maintaining adherence with therapy for the appropriate duration of therapy. For patients at high risk of bleeding, a shorter duration of DAPT may be warranted with the continuation of P2Y12 inhibitor instead of aspirin.

Continuation of DAPT beyond 12 months may be reasonable for patients at higher ischemic risk provided they also have a lower bleeding risk. This should be an individualized decision, considering both ischemic and bleeding risks. The DAPT risk score has been derived from the DAPT study and is supported by guidelines to aid in making decisions regarding prolonging DAPT beyond 12 months (Table 34-9).[107,108] A risk score of 2 or more suggests that prolonging therapy is favorable and would reduce ischemic events with perhaps only a modest increase in bleeding risk. Conversely, for those with a DAPT risk score less than 2, the risk for bleeding is anticipated to be greater than an ischemic benefit and the $P2Y_{12}$ inhibitor should be discontinued. The DAPT score was developed from a study comparing standard DAPT (12 months) to an extended duration of 30 months of therapy in patients who had PCI with intracoronary stenting for either SIHD or ACS and is not appropriate for determining DAPT duration shorter than 12 months. Further, 65% of patients enrolled in this study were administered clopidogrel and 35% were treated with prasugrel; ticagrelor was not used. Other risk prediction models are being developed and evaluated.

TABLE 34-9

Factors Used to Calculate DAPT Score and Predict Ischemic and Bleeding Events

Points	+2	+1	−1	−2
Clinical variables	CHF or LVEF less than 30% (0.30) Saphenous vein graft PCI	Current tobacco user Diabetes mellitus NSTEMI or STEMI at presentation Prior MI or PCI Stent diameter less than 3 mm Paclitaxel-eluting stent	Age 65-74	Age ≥75 years

Risk factors ordered from left to right include those with highest ischemic risk and highest point accrual to those with the highest bleeding risk and negative point accrual. A score of ≥2 favors prolonged DAPT; a score of <2 is of unfavorable risk/benefit. Total score ranges from −2 to 10.

Data from References [107,108].

Continued use of DAPT with ticagrelor beyond 12 months after ACS can be considered. One trial compared standard-dose ticagrelor to a reduced dose of 60 mg twice daily in combination with low-dose aspirin to aspirin alone in patients who had suffered an MI 1 to 3 years prior.[109] The continued DAPT with either dose of ticagrelor decreased the composite of CV death, MI, or stroke compared to aspirin alone. While major bleeding was increased in patients treated with ticagrelor compared to aspirin alone, there were fewer bleeds in the low-dose ticagrelor group compared to the standard dose. The lower dose of ticagrelor (60 mg twice daily) has not been studied in the first 12 months after ACS; therefore, only the 90 mg twice daily is appropriate for the first year after the index event.

Cholesterol Management

Statins

⑨ Following ACS, statins reduce total mortality, CV mortality, MI, and stroke. Results from landmark clinical trials have unequivocally demonstrated the value of statins in secondary prevention following MI and provide an approximate 1% reduction in risk of ASCVD event per 1% reduction in low-density lipoprotein cholesterol (LDL-C) over time.[101] Further, clinical trial results confirm the benefit of high-intensity statins initiated 1 to 10 days after ACS presentation. In a meta-analysis of randomized controlled clinical trials of patients with recent ACS (less than 14 days), statin therapy reduces mortality by 19%, with benefits observed after approximately 4 months of treatment.[110] Therefore, high-intensity statin therapy should be initiated during the index hospitalization once the patient has been stabilized and continued indefinitely. Risk reductions from high-intensity statin therapy occur regardless of cholesterol concentrations at presentation. Therefore, all patients with ACS should receive the highest dose of maximally tolerated statin, even those with “normal” LDL-C at baseline.[1,2,101]

In those patients who are already taking low- or moderate-intensity statin therapy at the time of ACS presentation, consideration should be given to switching to a high-intensity statin. For ACS patients with a history of statin intolerance or those at high risk for statin-related adverse effects (older patients, drug interaction, etc.), the use of moderate-intensity statins or lower doses of high-intensity statins may be considered.[101] Patients aged greater than 75 years may be prescribed a moderate-intensity statin as initial therapy because they are at higher risk of adverse drug effects and the data using high-dose statins in this patient subgroup are less robust.[101]

A lipid panel should be reassessed 4 to 6 weeks after initiation of therapy with the goal of a 50% reduction in LDL-C from baseline. Baseline lipid concentrations should be drawn as early as possible, ideally within the first 24 hours of ACS presentation, as phasic changes may occur that falsely lower total cholesterol, LDL-C, and high-density lipoprotein cholesterol. Triglycerides may be falsely elevated during this immediate period of ACS. See Chapter 32, “Dyslipidemia,” for a more detailed discussion on the management of patients with dyslipidemia.

Other Cholesterol-Lowering Therapies

Nonstatin therapies lower the risk of MACE in patients with ACS already receiving statin therapy and may be considered as add-on therapy in select patients. The combination of moderate-dose simvastatin and ezetimibe, a nonstatin, in patients with recent (within 10 days) ACS and an LDL-C level between 50 and 100 mg/dL (1.29 and 2.59 mmol/L) resulted in a modest reduction (6.4% relative risk reduction) in the rate of MACE compared to moderate-dose simvastatin alone.[111] Event rates were lower in patients who achieved lower LDL-C, suggesting a direct relationship between LDL-C and benefit. A new class of potent, injectable cholesterol-lowering drugs, the proprotein convertase subtilisin-kexin type 9 (PCSK9) inhibitors, lower the risk of MACE when added to high-intensity statin therapy in patients with recent ACS (within 1 to 12 months). Alirocumab reduced LDL-C by approximately 60% and the risk of MACE at 4 years by 15% compared to high-intensity statin therapy alone.[102] Another PCSK9 inhibitor, evolocumab, yielded similar reductions in LDL-C and MACE in patients with ASCVD, most of whom had a distant history of MI.[103] However, at the current cost of approximately $6,000 to $7,000 annually, the cost-effectiveness of PCSK9 inhibitors in this setting remains uncertain and may be dependent on baseline LDL-C.[101,112] Nevertheless, for patients with clinical ASCVD treated with maximally tolerated statin therapy at very high risk (eg, recent ACS event) and persistently elevated LDL-C (70 mg/dL [1.81 mmol/L]or greater), current guidelines suggest adding ezetimibe.[101] If LDL-C remains elevated despite maximally tolerated statin therapy and ezetimibe, the addition of a PCSK9 inhibitor is reasonable.[101]

ACE Inhibitors or Angiotensin Receptor Blockers

⑩ Following MI, the benefit of ACE inhibitors is through reductions in mortality, reinfarction rates, and HF, most likely through the prevention of adverse cardiac remodeling.[1,2,113,114] While the use of IV enalaprilat within 24 hours of MI should be avoided due to increased risk of adverse events, early administration (within 48 hours of presentation) of ACE inhibitors is associated with lower mortality within the first month of therapy with additional benefit observed during longer treatment durations.[113,114] Data supporting the use of ACE inhibitors is strongest for those with left ventricular dysfunction (LVEF 40% [0.40] or less) or in those who developed HF symptoms in the early phase of ACS.[113] Therefore, treatment with ACE inhibitor is recommended in all patients with MI and concomitant HFrEF, HTN, DM, or stable chronic kidney disease.[1,2,29] For patients without those comorbidities who suffer an MI, treatment with an ACE inhibitor is also reasonable.[1,29] Because they have a comparable benefit to ACE inhibitors in patients with MI, an ARB may be prescribed for those who cannot tolerate an ACE inhibitor.[1,2,29,115]

Although ACE inhibitors and ARBs are generally well-tolerated, it is important to monitor closely for the development of noteworthy adverse effects. The most common adverse effects associated with ACE inhibitors and ARBs are worsening renal function and hypotension. Hyperkalemia is also possible and is more likely in patients who develop acute kidney injury. Therefore, close monitoring of renal function, potassium levels, and blood pressure are warranted 1 to 2 weeks following initiation and dose adjustments. Although angioedema and chronic cough are possible with each of these therapies, both adverse effects are more common with ACE inhibitors and occur infrequently with ARBs.

Aldosterone Antagonists

⑩ To reduce mortality, administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 14 days following MI in all patients with left ventricular dysfunction (LVEF of 40% [0.40] or less) and either HF symptoms or DM treated with both an ACE inhibitor (or ARB) and β-blocker.[1,2,29] Aldosterone antagonists attenuate the adverse hemodynamic and metabolic effects from chronic excessive aldosterone production as well as the cardiac remodeling that occurs in patients with MI.[116] A recent meta-analysis of treatment with aldosterone antagonists in patients who suffered MI resulted in significantly higher LVEF, 26% lower risk for new or worsening HF, and an 18% reduction in the risk of both all-cause mortality and CV mortality.[116] Although mortality was lower in patients with and without HF treated with aldosterone antagonists, the difference was only significant in patients with HF.

Both eplerenone and spironolactone block the mineralocorticoid receptor to which aldosterone binds contributing to some of the observed adverse effects. Spironolactone is a nonspecific steroid hormone receptor antagonist that also binds progesterone and androgen receptors and can cause gynecomastia in men and menstrual irregularities in women.[19] In contrast, eplerenone is selective for the mineralocorticoid receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities.[19] In post-MI clinical trials, aldosterone antagonists have been associated with a more than twofold increase in the risk of hyperkalemia with an overall incidence of 11.6%.[116] Therefore, patients who are post-MI with serum potassium concentrations greater than 5 mmol/L (mEq/L) should not receive an aldosterone antagonist.[2] Additional contraindications for aldosterone antagonists include a serum creatinine greater than 2.5 mg/dL (221 µmol/L) for men or 2 mg/dL (177 µmol/L) for women, or CrCl less than 30 mL/min (0.5 mL/s).[2] Because of the increased risk of hyperkalemia, especially in patients with chronic kidney disease, both serum potassium and renal function should be monitored diligently: 3 days and 1 week after initiation or dose titration, then monthly for the first 3 months, and every 3 months thereafter. There are no data to support the use of the more selective but more expensive eplerenone over the generically available spironolactone unless a patient experiences gynecomastia, breast pain, or impotence while receiving spironolactone.

Nitroglycerin

All patients should be prescribed and instructed on the appropriate use of short-acting nitroglycerin, typically either sublingual tablets or lingual spray, to relieve acute anginal symptoms on an as-needed basis.[1,2] Appropriate patient education for patients prescribed short-acting nitroglycerin is provided in Chapter 33, "Stable Ischemic Heart Disease." Chronic long-acting nitrate therapy does not reduce MACE following ACS and its role is typically limited to the prevention of recurrent symptoms of angina for patients treated for ACS with significant coronary stenoses not amenable to revascularization who experience symptomatic SIHD. For patients with ACS for whom vasospasm is believed to be contributory, long-acting nitrates are recommended to treat and reduce the frequency of anginal episodes.[2]

EVALUATION OF THERAPEUTIC OUTCOMES

Evaluation of short-term efficacy focuses on the restoration or preservation of coronary blood flow, symptom relief, and prevention of MACE. Restoration of blood flow and relief of ischemia can be detected by resolution of the ischemic changes on ECG at the time of presentation, which should occur soon after revascularization. Although cTn levels may remain elevated for several days, for patients with MI, cTn levels should peak within 12 to 24 hours and should decline steadily thereafter once ischemia is relieved. More importantly, if blood flow is restored or preserved and the angina is managed effectively, the patients should have a resolution of symptoms rather quickly. In terms of MACE, monitoring for the development of complications from ACS (eg, HF, arrhythmias) should occur frequently. Lastly, assuring that evidence-based therapies that reduce the risk of MACE following ACS have been initiated in appropriate patients is critical.

Long-term evaluation of outcomes is directed largely at functional capacity and continued focus on risk reduction. Returning to and maintaining a high quality of life is an important goal following an ACS hospitalization. Patients should eventually be able to return to their activities of daily living, perhaps following a cardiac rehabilitation program to assist them with this goal. Additionally, patients should be monitored at every healthcare encounter for the development of adverse effects from ACS pharmacotherapy (Table 34-10). If patients show signs of adverse effects or intolerance, particularly serious adverse events such as bleeding or hypotension, the offending agent(s) may need to be discontinued until the symptoms have resolved. Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites. Oral antiplatelet agents are a leading cause of hospitalizations and ED visits for adverse drug reactions among senior citizens.[117] Patients should be counseled on the risks and sites of potential bleeding and should be told to seek medical care immediately if significant bleeding is noticed. If bleeding occurs while on chronic therapy, the patient should be referred to the prescribing physician as the severity of the bleed and the timing since index event (and presence of stent placement) may influence supportive measures and cessation of therapy.

TABLE 34-10

Therapeutic Drug Monitoring of Pharmacotherapy for ACS

Drug	Adverse Effects	Monitoring
Fibrinolytics	Bleeding (ICH)	Clinical signs of bleeding;[a] baseline aPTT, INR; Hgb, Hct, platelet count at baseline then daily; mental status every 2 hours for signs of ICH
Aspirin	Dyspepsia, GI bleeding	Clinical signs of bleeding;[a] GI upset; Hgb, Hct, and platelet count at baseline & every 6 months
$P2Y_{12}$ inhibitors	Bleeding, rash	Clinical signs of bleeding;[a] evidence of rash; Hgb, Hct, platelet count at baseline and every 6 months

	Ticagrelor: dyspnea, ventricular pauses, bradycardia	Ticagrelor: dyspnea, heart rate, telemetry during hospitalization
Glycoprotein IIb/IIIa inhibitors	Bleeding, thrombocytopenia (can be profound with abciximab)	Clinical signs of bleeding;[a] Hgb, Hct, and platelet count at baseline, 2 hours, then daily
		Eptifibatide and tirofiban: serum creatinine at baseline then daily
Anticoagulants	Bleeding	Clinical signs of bleeding;[a] baseline aPTT, INR; Hgb, Hct, platelet count at baseline then daily
	Unfractionated heparin and LMWH: heparin-induced thrombocytopenia	Unfractionated heparin: aPTT every 6 hours until two consecutive aPTT values are at goal, then every 24 hours; ACT during PCI
		Enoxaparin, bivalirudin, and fondaparinux: serum creatinine at baseline then daily
		Enoxaparin: may consider steady-state anti-Xa levels in special populations
β-blockers	Hypotension, heart failure, bradycardia, cardiogenic shock, AV block, exacerbation of asthma or reactive airway disease	Continuous telemetry (while hospitalized); blood pressure, heart rate, signs and symptoms of heart failure; monitor every 5 minutes before each IV bolus dose; monitor every shift while hospitalized then at each healthcare encounter after discharge
Nitroglycerin	Flushing, headache, hypotension, tachycardia	Blood pressure and heart rate; monitor every 5-15 minutes following dosage adjustment of intravenous nitroglycerin then every 1-2 hours; monitor every 5 minutes following administration of short-acting nitroglycerin
Morphine	Hypotension, respiratory depression, sedation, hypersensitivity	Blood pressure, heart rate, respiratory rate, sedation level 5 minutes after administration then every 1-2 hours for 4 hours after the last dose
Calcium channel blockers	Hypotension	Blood pressure, heart rate, every shift while hospitalized then at each healthcare encounter after discharge
	Verapamil and diltiazem: heart failure, cardiogenic shock, bradycardia, AV block	Verapamil and diltiazem: continuous telemetry (while hospitalized); signs and symptoms of heart failure every shift while hospitalized then at each healthcare encounter after discharge
Statins	GI discomfort, arthralgia, myalgia, musculoskeletal pain, hepatotoxicity	Liver function tests at baseline (prior to discharge) and if signs or symptoms of hepatotoxicity develop; creatinine kinase if severe myalgia or musculoskeletal symptoms occur; LDL-C at baseline, 4-12 weeks after initiation or dose adjustment, then every 3-12 months
Nonstatin therapies for cholesterol management	Ezetimibe and combination: GI discomfort, arthralgia, myalgia, musculoskeletal pain	Simvastatin/ezetimibe: liver function tests at baseline (prior to discharge) and if signs or symptoms of hepatotoxicity develop; creatinine kinase if severe myalgia or musculoskeletal symptoms occur; LDL-C at baseline, 4-12 weeks after initiation or dose adjustment, then every 3-12 months
	PCSK9 inhibitors: injection site pain,	PCSK9 inhibitors: LDL-C at baseline and 4-8 weeks after initiation or dose adjustment;

	hypersensitivity, nasopharyngitis	evaluation of injection site if injection site pain develops, signs and symptoms of hypersensitivity with each healthcare encounter
ACE inhibitors	Hypotension, hyperuricemia, hyperkalemia, worsening renal function, chronic cough, angioedema	Blood pressure every shift while hospitalized, 1-2 weeks after initiation or dose adjustment, then with each healthcare encounter; serum creatinine and potassium at baseline, 1-2 weeks after initiation, then every 6-12 months; signs and symptoms of angioedema or cough with each healthcare encounter
ARBs	Hypotension, hyperuricemia, hyperkalemia, worsening renal function	Blood pressure every shift while hospitalized, 1-2 weeks after initiation or dose adjustment, then with each healthcare encounter; serum creatinine and potassium at baseline, 1-2 weeks after initiation, then every 6-12 months
Aldosterone antagonist	Hyperkalemia, worsening renal function	Blood pressure every shift while hospitalized, 1-2 weeks after initiation or dose adjustment, then with each healthcare encounter; serum creatinine and potassium at baseline, after initiation or dose adjustment: at 3 days, 1 week, monthly for 3 months, then every 3 months

GI, gastrointestinal; Hct, hematocrit; Hgb, hemoglobin; ICH, intracranial hemorrhage; INR, international normalized ratio; LDL-C, low-density lipoprotein cholesterol; PCI, percutaneous coronary intervention; PCSK9, proprotein convertase subtilisin-kexin type 9.

[a] Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.

For long-term risk reduction, the focus centers on control of CAD risk factors and the appropriate use of and adherence to an evidence-based medication regimen known to reduce the risk of MACE. Lifestyle modifications should be reinforced during each healthcare encounter. Similarly, control of CAD risk factors should be assessed and interventions made to improve risk factor control, if necessary. Finally, it is important to reassess the evidence-based regimen to determine the need to either escalate (eg, add additional evidence-based ACS therapies or increase their doses) or de-escalate therapy (eg, consider discontinuation of $P2Y_{12}$ inhibitor after 12 months or β-blocker after 3 years in a post-MI patient with a normal LVEF).

Medication adherence must also be assessed during each healthcare encounter. Despite evidence to support mortality reduction with secondary prevention strategies, typically less than 50% of patients remain adherent at 1 year.[118] Because nonadherence with secondary prevention medications following ACS leads to poor CV outcomes, patients must receive thorough medication counseling (including counseling prior to hospital discharge) and be monitored for medication persistence.[1,2,104] Counseling should include assessments of health literacy level, barriers to adherence, access to medications, and understanding of instructions.[104] Additionally, patients and their caregivers should be provided written and verbal instructions about the purpose of each medication, changes to previous medication regimen, the optimal time to take each medication, new allergies or medication intolerances, need for a timely prescription fill after discharge, anticipated duration of therapy, consequences of nonadherence, common and/or serious adverse reactions that may develop, and drug–drug and drug–food interactions.[104] Early follow-up (within 6 weeks) after discharge has been associated with improved medication adherence and, for this reason, post-discharge follow-up is often scheduled within 1 to 2 weeks.[119]

CONCLUSION

For the majority of patients, the pathophysiology of ACS involves an acute disruption of an atherosclerotic plaque followed by platelet activation and aggregation leading to intracoronary thrombus formation. Myocardial ischemia ensues due to an acute imbalance between myocardial oxygen supply and demand and may lead to infarction depending on the severity and duration of thrombotic occlusion. Therefore, the acute pharmacotherapeutic management of ACS is focused on antiplatelet, anticoagulation, and anti-ischemic therapies. Appropriate selection of these agents depends upon patient presentation (eg, STEMI or NSTE-ACS), the decision for reperfusion (eg, PCI, fibrinolysis, or no reperfusion), and individual considerations for efficacy and safety associated with individual agents (eg, pharmacokinetic alterations, drug–drug interactions, contraindications). High-intensity statins should be initiated early and continued indefinitely for all patients with ACS without contraindications to lower LDL-C and stabilize atherosclerotic plaques. Long-term use of DAPT lowers the risk of MACE after ACS and maintains stent patency in patients who had intracoronary stent implantation during PCI. Neurohormonal blocking drugs such as β-blockers and inhibitors of the RAAS system are also associated with a lower risk of MACE and should be initiated prior to hospital discharge in appropriate patients. Each member of the healthcare team plays an important role in the patient care process for ACS, collecting and analyzing clinical information, collaborating in the development and implementation of the care plan, and evaluating therapeutic outcomes.

ABBREVIATIONS

ACC	American College of Cardiology
ACE	angiotensin-converting enzyme
ACS	acute coronary syndrome
ACT	activated clotting time
ADP	adenosine diphosphate
AHA	American Heart Association
aPTT	activated partial thromboplastin time
ARB	angiotensin receptor blocker
ASCVD	atherosclerotic cardiovascular disease
AT	antithrombin
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CCB	calcium channel blocker
COX	cyclooxygenase
CrCl	creatinine clearance
cTn	cardiac troponin
CV	cardiovascular
CYP	cytochrome P450
DAPT	dual antiplatelet therapy
DHP	dihydropyridine
DM	diabetes mellitus
ECG	electrocardiogram
ED	emergency department

EMS	emergency medical services
ENT	equilibrative nucleoside transporter
GI	gastrointestinal
GP	glycoprotein
GRACE	Global Registry of Acute Coronary Events
HEART	History, ECG, age, risk factors, and troponin
HF	heart failure
HFrEF	heart failure with reduced ejection fraction
HIT	heparin-induced thrombocytopenia
HTN	hypertension
ICH	intracranial hemorrhage
IV	intravenous
LBBB	left bundle branch block
LDL-C	low-density lipoprotein cholesterol
LMWH	low-molecular-weight heparin
LVEF	left ventricular ejection fraction
MACE	major adverse cardiovascular events
MI	myocardial infarction
MONA	morphine, oxygen, nitroglycerin, aspirin
NSTE-ACS	non-ST-segment elevation acute coronary syndromes
NSTEMI	non-ST-segment elevation myocardial infarction
PAR	protease-activated receptor
PCI	percutaneous coronary intervention
PCSK9	proprotein convertase subtilisin-kexin type 9
RAAS	renin–angiotensin–aldosterone system
SCr	serum creatinine

SIHD	stable ischemic heart disease
SNS	sympathetic nervous system
STEMI	ST-segment-elevation myocardial infarction
SC	subcutaneous
TIMI	thrombolysis in myocardial infarction
UA	unstable angina

SELF-ASSESSMENT QUESTIONS

1. A 47-year-old patient (weight 78 kg) with a history of stable ischemic heart disease (SIHD) presents with substernal chest pressure. His electrocardiogram (ECG) shows ST-segment depression. His initial troponin (cTn) is elevated. The patient undergoes percutaneous coronary intervention (PCI) with two drug-eluting stents. According to practice guidelines, in addition to aspirin 81 mg daily, which $P2Y_{12}$ inhibitor regimen is most appropriate for this patient at discharge?

   A. Clopidogrel 75 mg daily for 6 months

   B. Prasugrel 10 mg daily for 1 year

   C. Ticagrelor 60 mg twice daily for 1 year

   D. Ticagrelor 90 mg twice daily for 6 months

2. A patient presents to the emergency department (ED) with lower back pain, diaphoresis, and nausea and is treated for unstable angina with aspirin 325 mg and intravenous (IV) unfractionated heparin. Which option depicts the most appropriate monitoring of parameters during IV unfractionated heparin administration?

A. Activated partial thromboplastin time (aPTT) every 3 hours until therapeutic

B. aPTT every 6 hours until therapeutic

C. Activated clotting time (ACT) every 12 hours until therapeutic

D. ACT daily until therapeutic

3. A 72-year-old African American patient presents with chest pain after a recent drug-eluting stent placement 3 months ago and is treated for ST-segment elevation myocardial infarction (STEMI) due to in-stent thrombosis with successful PCI. The patient reports compliance with his dual antiplatelet therapy, which consisted of clopidogrel 75 mg daily and aspirin 81 mg daily. He also takes ranitidine for indigestion-related symptoms. Which of the following best describes a rationale for clopidogrel's reduced activity in this patient?

   A. Presence of CYP3A4 polymorphism

   B. Presence of CYP2C19 polymorphism

   C. Drug interaction with ranitidine

   D. Improper clopidogrel dose

4. A 55-year-old African American patient with hypertension (HTN) but no history of coronary artery disease presents to the ED for one episode of back pain accompanied by nausea and vomiting which resolved after one dose of sublingual nitroglycerin. Social history is unremarkable. Home medications include chlorthalidone 25 mg daily and amlodipine 5 mg daily. ECG shows some ST-segment depression. Laboratory values are within normal limits and her estimated creatinine clearance (CrCl) is 67 mL/min (1.12 mL/s). cTn is undetectable. Weight = 80 Kg. Based on the patient's Thrombolysis in Myocardial Infarction (TIMI) risk score, which is the most appropriate strategy for this patient?

   A. Early invasive approach

   B. Fibrinolytic therapy

   C. Ischemia-guided approach

   D. Primary PCI

5. A patient with a past medical history significant for diabetes mellitus (DM) is hospitalized for STEMI, has PCI performed, and is now being prepared for discharge. Estimated CrCl is 50 mL/min (0.83 mL/s), and LDL-C is 79 mg/dL (2.05 mmol/L). Pertinent laboratory data include sodium 134 mEq/L (mmol/L), potassium 3.4 mEq/L (mmol/L), and creatinine 1.5 mg/dL (133 µmol/L). Blood pressure is 115/80 mm Hg and heart rate is 78 beats per minute. Current medications include aspirin 81 mg daily, atorvastatin 80 mg daily, metoprolol succinate 50 mg daily, lisinopril 10 mg daily, and ticagrelor 90 mg twice daily. Echocardiogram reveals a left ventricular ejection fraction (LVEF) of 25% (0.25). Which guideline-directed medical therapy would be best to add to this patient's regimen?

   A. Alirocumab 75 mg SC every 2 weeks

   B. Diltiazem extended-release 180 mg daily

   C. Losartan 25 mg daily

   D. Spironolactone 25 mg daily

6. A 57-year-old patient (weight 92 kg) with a history of SIHD presents with a 4-hour history of substernal chest pressure. The ECG shows 3 mm ST-segment elevation in leads V2–V4. The initial cTn is 5.2 ng/mL (mcg/L), SCr 1.1 mg/dL (97 µmol/L), and potassium 3.7 mEq/L (mmol/L). The nearest hospital with catheterization laboratory facilities is 2.5 hours away by ambulance. Blood pressure is 210/85 mm Hg at present. Which of the following is the most appropriate reperfusion strategy for this patient?

A. Blood pressure must be lowered before fibrinolytic therapy is considered.

B. Primary PCI is preferred over fibrinolytic therapy in this patient.

C. Tenecteplase 50 mg IVP once.

D. Reteplase 10 units IVP once.

Please use the following case to answer questions 7 to 9.

RJ is a 68-year-old patient (weight 100 kg) who presents to the hospital with consistent substernal chest pain rated 8 out 10 for the last 4 hours that radiates to his left arm and up into his jaw. Past medical history includes DM, HTN, ischemic stroke, depression, and dyslipidemia. ECG reveals ST-segment depression and the initial cTn is elevated. All other laboratory values are within normal limits including renal and liver function. Blood pressure is 124/74 mm Hg and heart rate is 78 beats per minute. RJ has received 3 doses of sublingual nitroglycerin with minimal relief. The plan is for RJ to go to the catheterization laboratory for PCI and stent placement in the next 12 hours.

7. Which of the following represents the most likely pathophysiologic mechanism of RJ's ACS event?

   A. Vasospasm

   B. Ruptured atherosclerotic plaque

   C. Increase in myocardial oxygen demand in the setting of a fixed decrease in supply

   D. Smooth muscle cell proliferation

8. Which of the following represents the most appropriate antiplatelet regimen, in addition to aspirin, for RJ while he is still in the ED before going to PCI?

   A. Clopidogrel 300 mg, followed by 75 mg daily

   B. Ticagrelor 180 mg, followed by 90 mg twice daily

   C. Prasugrel 60 mg, followed by 10 mg daily

   D. Eptifibatide 180 mcg/kg IV bolus × 2 given 10 minutes apart, followed by 2 mcg/kg/min IV infusion started after first bolus

9. Which of the following represents the most appropriate anticoagulant regimen to initiate in the ED?

   A. Unfractionated heparin 8,000 units IV bolus, then 1,800 units/hr IV infusion

   B. Fondaparinux 5 mg subcutaneously (SC) every 24 hours

   C. Bivalirudin 0.10 mg/kg IV bolus, followed by 0.25 mg/kg/hr IV infusion

   D. Enoxaparin 100 mg SC every 12 hours

10. Which of the following substances is central in the clotting cascade as well as involved in platelet activation and aggregation?

   A. Von Willebrand factor

   B. Collagen

   C. Thrombin

   D. Tissue factor

11. A 72-year-old patient presents to the ED with chest tightness that started 8 hours ago. This is the third episode, is associated with diaphoresis and dyspnea, and is refractory to sublingual nitroglycerin. Blood pressure is 114/78 mm Hg, heart rate is 112 bpm, respiratory rate is 26 breaths/min, and oxygen saturation is 89% (0.89) on room air. ECG shows 2-mm ST-segment depression. Bilateral crackles are noted at the bases bilaterally on physical examination. Which of the following acute supportive measures should be avoided in this patient?

    A. IV metoprolol

    B. IV morphine

    C. IV nitroglycerin

    D. Oxygen

12. A 54-year-old patient presents to the ED complaining of acute-onset chest pain radiating down his left arm, which started 2 hours ago. He admits to cocaine ingestion just prior to the onset of symptoms. Blood pressure is 220/108 mm Hg, heart rate is 108 bpm, and oxygen saturation is 98% (0.98) on room air. ECG shows 1 mm ST-segment depression. Laboratory values are pending. Which of the following acute supporting measures is most appropriate at this time?

    A. IV metoprolol

    B. IV morphine

    C. IV nitroglycerin

    D. Oxygen

13. A patient treated for STEMI complicated by symptomatic heart failure (LVEF 35% [0.35]) is being started on eplerenone. Baseline serum creatinine and potassium were within normal limits. When should serum creatinine and potassium levels be reassessed?

    A. 3 days

    B. 1 week

    C. 2 weeks

    D. 1 month

14. A patient is treated for NSTEMI. An echocardiogram reveals an LVEF of 20% (0.20). The patient is hemodynamically stable and being discharged on the following medications: aspirin 81 mg daily, prasugrel 10 mg daily, rosuvastatin 40 mg daily, carvedilol 3.125 mg twice daily, ramipril 10 mg daily, and spironolactone 25 mg daily. What is the most appropriate duration of carvedilol therapy for this patient?

    A. 6 months

    B. 1 year

    C. 3 years

    D. Indefinitely

15. EP, a 66-year-old patient, complains of sudden onset tightness in his chest and jaw, shortness of breath, diaphoresis and headache that began 3 hours ago when shoveling snow on the patio. The patient has no known medical problems, takes no medications, and has no known drug allergies. Blood pressure is 194/98 mmHg, heart rate 98 bpm. Electrocardiogram reveals T wave inversion in 2 contiguous leads. Creatinine is 1.1 mg/dL (97 µmol/L; creatinine clearance 77 mL/min [1.28 mL/s]) and cardiac troponin is 4.6 ng/mL (mcg/L; normal < 0.02 ng/mL [mcg/L]). Which of the following antithrombotic therapies should be avoided in this patient?

    A. Alteplase

B. Aspirin

C. Enoxaparin

D. Ticagrelor

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The 2014 NSTE-ACS guideline gives a class I recommendation for clopidogrel, prasugrel, or ticagrelor in the ACS setting with PCI and stent placement (Table 34-5). After any ACS event (regardless of PCI with stent placement), the preferred duration for dual antiplatelet therapy is at least 12 months (A and D are incorrect). B is correct because prasugrel is an appropriate antiplatelet in this setting, is dosed correctly at a maintenance of 10 mg, and is continued for the correct time frame of 12 months post ACS. C is incorrect because the appropriate ticagrelor dose during the initial 12 months following an ACS event is 90 mg (not 60 mg) twice daily.

2. **B.** Unfractionated heparin may be monitored by aPTT, anti-Xa, or ACT for therapeutic accuracy (Table 34-10). In patients going to the cath lab, an activated clotting time (ACT) is normal, as it can be tested at the bedside with relatively instant results during the procedure. Conversely, an ACT is not measured in a patient such as this who is managed with an ischemia-guided approach (ie, not going to the cath lab) (C and D are incorrect). In patients receiving an unfractionated heparin infusion, an aPTT should be monitored every 6 hours until therapeutic and daily thereafter (A is incorrect). B represents the correct time frame for aPTT monitoring. In addition, hemoglobin, hematocrit, and platelets (at least every other day if not more often) should be monitored in patients receiving unfractionated heparin infusions.

3. **B.** Reduced efficacy can occur with clopidogrel for a number of reasons, non-adherence to therapy being the most important (see "Clopidogrel" section). When patients report being adherent with this daily therapy, reduced activity can occur because of the presence of a genetic polymorphism of the CYP2C19 gene (B is correct), responsible for converting clopidogrel into its active form, not CYP3A4 (A is incorrect). Drug interactions have been theorized to reduce activity as well, especially with potent inhibitors of CYP2C19 such as esomeprazole and omeprazole. But, ranitidine is not known to interact with clopidogrel (C is incorrect). Finally, although higher doses of clopidogrel have been studied to overcome resistance, those dosing strategies are not recommended (D is incorrect).

4. **C.** This patient has a TIMI risk score of 1 (ST-segment depression on ECG) indicating low-risk (Table 34-1). Women who present with NSTE-ACS without cTn elevation and low-risk features, like the patient in this case, should not undergo early invasive treatment because of the lack of benefit and potential for harm (Class III) (A is incorrect). In the absence of ST-segment elevation or new-onset left bundle branch block, immediate reperfusion with either a fibrinolytic (B) or primary PCI (D) is incorrect. Women with low-risk features should be treated with an ischemia-guided approach (Fig. 34-2), where she should be treated medically while monitoring her symptoms (C is correct).

5. **D.** To reduce mortality, administration of a mineralocorticoid receptor antagonist, such as spironolactone (D is correct) should be considered within the first 14 days of post-myocardial infarction in patients who are already receiving an ACE inhibitor (or ARB) and a β-blocker in patients who have a LVEF of 40% (0.40) or less and either HF symptoms or DM as long as no contraindications exist (Fig. 34-3 and Table 34-8). C is incorrect because this patient is already receiving an ACE inhibitor and the addition of an ARB to an ACE will increase risk for adverse events but not reduce mortality further. Diltiazem is not indicated because the patient is already receiving metoprolol succinate and does not have refractory symptoms (B is incorrect). A is not correct because additional lowering of LDL-C is not necessary and the patient is already treated with high-intensity statin therapy.

6. **A.** Fibrinolytic therapy is indicated and should be administered for patients with STEMI when PCI cannot be performed within 120 minutes (Table 34-3). Because the nearest cath lab is 2.5 hours away, this patient would benefit from fibrinolytic therapy. (B is incorrect.) However, his current blood pressure of 210/85 mm Hg represents a relative contraindication to fibrinolytic administration (C and D are incorrect; Table 34-3). Blood pressure must be lowered prior to administration in order to reduce risk for bleeding complications from therapy, including intracranial hemorrhage (A is correct). If systolic blood pressure is successfully lowered to <185 mm Hg, C and D become correct options. However, only the dosing in answer C would be correct (Table 34-4). Reteplase is given as a double bolus, not a one-time dose (D is incorrect; Table 34-4).

7. **B.** The most common pathophysiologic mechanism creating an acute coronary syndrome is rupture atherosclerotic plaque, making B correct (see "Pathophysiology" section). While vasospasm can produce an ACS event, it is much less likely and when it occurs without atherosclerosis, it typically occurs in younger patients. C is incorrect as this is the main pathophysiologic mechanism in patients with stable ischemic heart disease and not for an ACS event. D is also not correct as this is the main mechanism of restenosis of previously revascularized vessels and does not typically present as an

ACS event due to the process taking 3 to 6 months to occur.

8. **B.** While the guidelines do say that clopidogrel is an acceptable option, the use of ticagrelor and prasugrel are preferred in patients undergoing PCI due to better efficacy in the head-to-head trials. When clopidogrel is used in patient undergoing PCI, the 600 mg loading dose should be used instead of the 300 mg loading dose (Table 34-5). Therefore, A is incorrect and B is correct. The dose of prasugrel is correct, but prasugrel is contraindicated in patients with a history of stroke or transient ischemic attack due to excessive bleeding and no additional efficacy. Therefore, C is incorrect. If the patient is preloaded with a more potent $P2Y_{12}$ inhibitor such as ticagrelor or prasugrel, the use of a GP IIb/IIIa inhibitor adds unknown value. GP IIb/IIIa inhibitors are also best used at the time of PCI instead of upstream use in the emergency department, making D incorrect.[12]

9. **D.** While all of these anticoagulants can be used in patients with NSTE-ASC, they are not all appropriate or appropriately dosed in this patient. Initial unfractionated heparin bolus doses are capped at 4,000 units and initial infusion rates are capped at 1,000 units per hour for patients with ACS (Table 34-7). The dosing in A is incorrect as this represents the dosing of unfractionated heparin in patients with venous thromboembolism. Fondaparinux is generally not used in patients undergoing PCI due to the increase in catheter thrombosis. The dose is also too high for the setting of ACS. Dosing should be 2.5 mg and not 5 mg (Table 34-7), making B incorrect. Bivalirudin is started at the time of PCI and not in the emergency department, making C incorrect. Enoxaparin dosed at 1 mg/kg every 12 hours is an acceptable option in the guidelines (Table 34-7), and therefore, D is correct.

10. **C.** (See "Pathophysiology" section.) The von Willebrand factor in endothelial cells is mainly involved in the initial adhesion of platelet to the area of atherosclerotic plaque rupture, but has no role in the clotting cascade. Therefore, A is incorrect. Collagen is responsible for the stability of the fibrous cap on the atherosclerotic plaque, as well as platelet adhesion at the site of plaque rupture, and a very potent platelet activator. It does not have a role in the clotting cascade, making B incorrect. Thrombin is the central component of the clotting cascade and responsible for multiple positive feedback loops to potentiate the clotting cascade. All currently used anticoagulants either target thrombin directly or its production. Thrombin is also a very potent platelet activator. Being an important link between the two pathways, C is correct. Tissue factor released from damaged endothelial cells is responsible for initiation of the extrinsic clotting cascade, but does not impact platelets, making D incorrect.

11. **A.** This patient has evidence of acute heart failure (bilateral basilar crackles) and several risk factors for the development of cardiogenic shock (age >70 years, systolic BP <120 mm Hg, heart rate > 110 bpm; Table 34-2). Therefore, IV beta-blockers should be avoided (A is correct). Because this patient's symptoms are refractory to sublingual nitroglycerin, both IV morphine (B) and IV nitroglycerin (C) are reasonable supportive care measures in this patient (Table 34-2); avoiding them is incorrect. This patient is hypoxic; therefore, avoidance of oxygen (D) would be incorrect.

12. **C.** Because this patient is presenting with ACS following acute cocaine ingestion and is also experiencing acute, uncontrolled HTN, the most appropriate acute supportive measure is IV nitroglycerin (C is correct, see "Nitroglycerin" section). Because of the cocaine ingestion, the use of IV beta-blockers is not recommended (A is incorrect). IV morphine is not appropriate at this time because his symptoms are not refractory; he has not yet been given anything to treat his symptoms (B is incorrect). Oxygen saturation is acceptable at 98% (0.98); therefore, supplemental oxygen is unnecessary (D is incorrect).

13. **A.** Because of the risk of hyperkalemia, patients initiated on aldosterone antagonists should have their serum creatinine and potassium levels monitored closely: at 3 days, 1 week, and at least monthly for the first 3 months (Table 34-10). Therefore, A is correct. While a patient initiated on an aldosterone antagonist should have creatinine and potassium measured at 1 week (B) and 1 month (D), the initial reassessment should occur at 3 days; therefore, these answers are incorrect. Two weeks would not be soon enough to monitor for the development of hyperkalemia (C is incorrect).

14. **D.** Because the patient has had an MI and has HFrEF (LVEF 20% [0.20]), beta-blocker therapy (carvedilol) should be continued indefinitely (D is correct). Three years of therapy would only be required if the LVEF were normal (C is incorrect). Although there is some debate about only 1 year of beta-blocker therapy in patients with ACS and normal LVEF, guidelines do not recommend durations of beta-blocker therapy less than 3 years (A and B are incorrect).

15. **A.** Because the patient does not have ST-elevation on the ECG, there is no indication for fibrinolytic therapy with alteplase (A is correct). Aspirin, enoxaparin, and ticagrelor would all be plausible therapies in this patient; avoidance would be unnecessary (B, C, and D are incorrect).

Chapter 36: Chronic Heart Failure

Robert B. Parker; Jo Ellen Rodgers

KEY CONCEPTS

KEY CONCEPTS

① Heart failure (HF) is a clinical syndrome associated with symptoms and/or signs due to abnormalities in cardiac structure and/or function substantiated by the presence of increased natriuretic peptide plasma concentrations or objective evidence of pulmonary or systemic congestion of cardiogenic origin. The left ventricular ejection fraction (LVEF) is used to classify patients into four different types of HF, the two primary classifications being heart failure with reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF). Patients with HFrEF or HFpEF commonly present with signs and symptoms of fluid overload.

② With HFpEF, systolic function is preserved. In contrast, the heart does not relax nor fill sufficiently resulting in compromised diastolic function. Despite the activation of similar neurohormonal systems as HFrEF, patients with HFpEF are often treated differently than those with HFrEF. Most of the pharmacotherapies known to benefit patients with HFrEF have been less beneficial in HFpEF. Targeting the underlying cause, most commonly uncontrolled hypertension, has been the primary strategy for managing patient with HFpEF. However, recent trials have identified new therapies that benefit patients with HFpEF.

③ In HFrEF, systolic dysfunction results in a decline in cardiac output leading to the activation of a number of neurohormonal compensatory responses that attempt to maintain adequate cardiac output. These responses include activation of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS) and other systems. These compensatory mechanisms play an important role in ventricular remodeling and contribute to the progression of HF. Importantly, pharmacotherapy targeted at antagonizing this neurohormonal activation slows the progression of HFrEF and improves survival.

④ Most patients with HFrEF should be routinely treated with guideline-directed medical therapy (GDMT) — medications known to reduce mortality in these patients. GDMT includes four medication classes: an angiotensin receptor II receptor blocker/neprilysin inhibitor (ARNI) or angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB), an evidence-based β-blocker, an aldosterone antagonist, and a sodium-glucose cotransporter-2 (SGLT2) inhibitor. In patients with HFrEF, GDMT dosing should be titrated to achieve target doses known to be effective in randomized clinical trials. Patients with HFpEF may benefit from an ARNI and SGLT2 inhibitor.

⑤ The ARNI, sacubitril/valsartan, is the only therapy approved to treat patients with HFrEF and many with HFpEF. In patients with HFrEF, ARNI is preferred over either ACE inhibitors or ARBs to improve survival, slow disease progression, reduce hospitalizations, and improve quality of life. Patients receiving ACE inhibitors or ARBs can be switched to ARNI or ARNI can be used as initial treatment in patients with newly detected HFrEF without previous exposure to ACE inhibitors or ARBs. The doses for these agents should be targeted at those shown in clinical trials to improve survival.

⑥ The β-blockers carvedilol, metoprolol succinate, and bisoprolol prolong survival, decrease hospitalizations, reduce the need for transplantation, and promote "reverse remodeling" of the left ventricle. These agents are recommended for all patients with HFrEF unless contraindicated. Therapy must be instituted at low doses, with slow upward titration to the target dose.

⑦ The aldosterone antagonists prolong survival and decrease hospitalizations in patients with HFrEF and New York Heart Association (NYHA) class II to IV symptoms. These agents may be used provided that potassium and renal function can be carefully monitored. The aldosterone antagonists may be considered to reduce the risk of hospitalization in patients with HFpEF.

⑧ The SGLT2 inhibitors dapagliflozin or empagliflozin reduce the risk of cardiovascular death, hospitalization, and worsening HF in patients with HFrEF. In addition, empagliflozin reduces the composite outcome of cardiovascular death or HF hospitalization in patients with HFpEF. In both HFrEF and HFpEF, these benefits were demonstrated in patients with and without type 2 diabetes. SGLT2 inhibitors require assessment of renal function prior to initiation.

⑨ Although chronic loop diuretic therapy frequently is used in patients with HFrEF or HFpEF, it is not mandatory. Diuretic therapy is required only in those patients with peripheral edema and/or pulmonary congestion. Many patients will need continued diuretic therapy to maintain euvolemia after fluid overload is resolved.

⑩ The combination of hydralazine and nitrates improves the composite endpoint of mortality, hospitalizations for HF, and quality of life in Black patients receiving GDMT for HFrEF. Hydralazine and nitrates should be used in Black patients with persistent symptoms despite GDMT. Hydralazine and a nitrate might be reasonable in patients unable to tolerate either an ACE inhibitor or ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.

⑪ Other therapies including digoxin, ivabradine, and vericiguat may be used in select patients with HFrEF to improve symptoms or reduce the risk of hospitalization.

BEYOND THE BOOK

BEYOND THE BOOK

What the video by Osmosis regarding congestive heart failure (CHF)—systolic, diastolic, left side, right side, and symptoms.. This video provides an overview of the pathophysiology of heart failure due to both systolic and diastolic dysfunction. It also explains how heart failure symptoms relate to the underlying pathophysiology. A thorough understanding of heart failure pathophysiology and symptoms is key for students understanding how pharmacotherapy affects symptoms and improves overall outcomes. This will assist students in understanding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

① Heart failure (HF) is a clinical syndrome associated with symptoms and/or signs due to abnormalities in cardiac structure and/or function substantiated by the presence of increased natriuretic peptide plasma concentrations or objective evidence of pulmonary or systemic congestion of cardiogenic origin.[1] HF is the final common pathway for numerous cardiac disorders including those affecting the pericardium, heart valves, and myocardium. HF may be caused by an abnormality that affects cardiac systolic function, diastolic function, or both. Making the distinction is important because the treatment of HF may be quite different depending on whether the predominant mechanism of the disorder is systolic (ie, reduced left ventricular ejection fraction [LVEF]), now referred to as heart failure with reduced ejection fraction (HFrEF) or diastolic dysfunction (HF with normal LVEF, termed heart failure with preserved ejection fraction, HFpEF). Approximately 50% of patients with HF have HFpEF with disturbances in relaxation (lusitropic) properties of the heart or diastolic dysfunction.[2] However, regardless of the etiology of HF, the principal clinical manifestations (fatigue, dyspnea, and often volume overload) are similar and appear to be independent of the initial cause. This chapter focuses on the treatment of patients with chronic HFrEF and HFpEF. Chapter 37, "Acute Decompensated Heart Failure," discusses the treatment of acute decompensated HF.

EPIDEMIOLOGY

HF is an epidemic public health problem in the United States.[2] Approximately 6 million Americans have HF with 1,000,000 new cases diagnosed each year.[2] Unlike most other cardiovascular diseases, the incidence and prevalence of HF are increasing and are expected to continue to increase over the the next few decades as the population ages. A large majority of patients with HF are elderly, with multiple comorbid conditions that influence morbidity and mortality.[2] Improved survival from the treatment of comorbidities such as hypertension and coronary artery disease as well as the more widespread use of device therapy including implantable cardioverter-defibrillators and cardiac resynchronization therapy are likely contributors to the increased incidence and prevalence of HF.[2,3] Annual hospital discharges for HF are approximately 800,000, and HF is a common hospital discharge diagnosis in individuals over age 65 years.[2] The disorder also has a tremendous economic impact, with this expected to increase markedly as the baby-boom generation ages. The annual expenditures for HF were over $30 billion, with estimates approaching $70 billion by 2030.[2] Thus, HF is a major medical problem, with a substantial economic impact that is expected to become even more significant as the population ages.

Marked racial and ethnic disparities in the epidemiology and clinical outcomes of HF exist.[2,4] Black patients are at the highest risk of developing and dying from HF (HFrEF or HFpEF) and are hospitalized at higher rates than White patients.[2,4] The reasons for these differences are multifactorial and represent a complex mix of higher prevalence of cardiovascular risk factors (hypertension, diabetes, obesity, chronic kidney disease), genetic susceptibility, access to care, socioeconomic factors, social determinants of health, and implicit biases in healthcare providers and systems.[4]

Despite prodigious advances in our understanding of the etiology, pathophysiology, and pharmacotherapy of HF, the prognosis for patients with this disorder remains grim. Although the mortality rates have declined over the last 50 years, the overall 5-year survival remains approximately 42% for all patients with a diagnosis of HF, with mortality increasing with symptom severity.[2] Death is classified as sudden in about 40% of patients, implicating serious ventricular arrhythmias as the underlying cause. Factors affecting the prognosis of patients with HF include, but are not limited to, age, gender, LVEF, renal function, natriuretic peptide plasma concentrations, diabetes, metabolic syndrome, the extent of underlying coronary artery disease, blood pressure (BP), HF etiology, and drug or device therapy.[2] Models incorporating these and other factors enable clinicians to develop reliable estimates of an individual patient's prognosis.[5–7]

CLASSIFICATION AND ETIOLOGY

① The LVEF is used to classify patients with HF as it identifies specific groups in which guideline-directed medical therapy (GDMT) improves key clinical outcomes such as mortality, hospitalization, and symptoms. Four classifications of HF are proposed: (1) HFrEF; (2) HF with mildly reduced ejection fraction (HFmrEF); (3) HFpEF; and (4) HF with improved EF (HFimpEF) (Table 36-1).[1]

TABLE 36-1

Classification of Heart Failure According to Left Ventricular Ejection Fraction

HF with reduced EF (HFrEF)	HF with LVEF ≤ 40% (0.4)
HF with mildly reduced EF (HFmrEF)	HF with LVEF 41%-49% (0.41-0.49)
HF with preserved EF (HFpEF)	HF with LVEF ≥ 50% (0.5)
HF with improved EF (HFimpEF)	HF with baseline LVEF ≤ 40% (0.4), a ≥ 10 point increase from baseline LVEF, and a second measurement of LVEF > 40% (0.4)

HF, heart failure; LVEF, left ventricular ejection fraction.

Data from Reference [1].

HF can result from any disorder that affects the ability of the heart to contract (systolic function) and/or relax (diastolic dysfunction); common causes of HF are shown in Table 36-2.[8] HFrEF is the classic, more familiar form of the disorder although up to 50% of patients with HF have preserved left ventricular systolic function with presumed diastolic dysfunction, now termed HFpEF.[9] Patients with HFpEF typically are elderly, female, and obese, and have hypertension (HTN), atrial fibrillation, or diabetes.[2,10] Mortality is lower in patients with HFpEF compared to patients with HFrEF, despite HFpEF patients being older.[10]

TABLE 36-2

Common Causes of Chronic Heart Failure

Heart failure with reduced ejection fraction (HFrEF)

- Coronary artery disease (eg, myocardial infarction or ischemia)
- Dilated cardiomyopathies (eg, drug-induced, viral infections, postpartum)
- Pressure overload (eg, systemic or pulmonary hypertension, aortic, or pulmonic valve stenosis)
- Volume overload (eg, valvular regurgitation, shunts, high-output states)

Heart failure with preserved ejection fraction (HFpEF)

- Increased ventricular stiffness
  - Ventricular hypertrophy (eg, hypertrophic cardiomyopathy, hypertension)
  - Infiltrative myocardial diseases (eg, amyloidosis, sarcoidosis, endomyocardial fibrosis)
  - Myocardial infarction or ischemia
- Mitral or tricuspid valve stenosis
- Pericardial disease (eg, pericarditis, pericardial tamponade)

Data from Reference [8].

Patients with LVEF between the HFrEF and HFpEF range are considered as "HF with mid-range EF" or "HF with mildly-reduced EF" (HFmrEF).[1] HFmrEF may represent patients with prior HFrEF but with improved LVEF or patients with deterioration in LVEF possibly progressing to HFrEF. To improve the specificity of diagnosing HFmrEF and HFpEF, the clinical diagnosis of HF in these EF categories should be further supported by objective measures. In addition, patients with HF with baseline LVEF < 40% (0.4) who experience a greater than 10 point increase from baseline LVEF and a subsequent measurement of LVEF > 40% (0.4) may be classified as HFimpEF. Both characteristics of and optimal management of patients with HFmrEF and HFimpEF are areas of ongoing investigations.

Coronary artery disease is the most common cause of HFrEF, accounting for up to 75% of cases.[8] Myocardial infarction (MI) leads to a reduction in muscle mass due to the death of affected myocardial cells. The degree to which contractility is impaired depends on the size of the infarction. To attempt to maintain cardiac output (CO), the surviving myocardium undergoes a compensatory remodeling, thus beginning the maladaptive process that initiates the HF syndrome and leads to further injury to the heart. This is discussed in greater detail in the "Pathophysiology" section. Myocardial ischemia and infarction also affect the diastolic properties of the heart by increasing ventricular stiffness and slowing ventricular relaxation. Thus, MI frequently results in systolic and diastolic dysfunctions.

Impaired systolic function is a cardinal feature of dilated cardiomyopathies. Although the cause of reduced contractility frequently is unknown, abnormalities such as interstitial fibrosis, cellular infiltrates, cellular hypertrophy, and myocardial cell degeneration are seen commonly on histologic examination. Inherited forms of dilated as well as hypertrophic cardiomyopathies may also occur.[8]

Pressure or volume overload causes ventricular hypertrophy, which attempts to return contractility to a near-normal state. If the pressure or volume overload persists, the remodeling process results in alterations in the geometry of the hypertrophied myocardial cells and is accompanied by increased collagen deposition in the extracellular matrix. Thus, both systolic and diastolic functions may be impaired.[11] Examples of pressure overload include systemic or pulmonary HTN and valvular heart disease.

HTN remains an important cause and/or contributor to both HFrEF and HFpEF in many patients, particularly women, the elderly, and African Americans.[2,4,8] The role of HTN should not be underestimated because it is an important risk factor for ischemic heart disease and is present in a high percentage of patients with coronary artery disease. HF is a largely preventable disorder; control of lifestyle risk factors (eg, HTN, coronary heart disease, smoking, obesity, physical activity, diabetes) is key to minimizing the risk of HF development. Two causes of HF that have been increasingly recognized include amyloidosis and cardiotoxicity with cancer therapies.

PATHOPHYSIOLOGY

Normal Cardiac Function

To understand the pathophysiologic processes in HF, a basic understanding of normal cardiac function is necessary. CO is defined as the volume of blood ejected per unit time (L/min) and is the product of heart rate (HR) and stroke volume (SV):

$$\mathrm{CO} = \mathrm{HR} \times \mathrm{SV}$$

CO=HR×SV

The relationship between CO and mean arterial pressure (MAP) is as follows:

$$\mathrm{MAP} = \mathrm{CO} \times \text{systemic vascular resistance}(\mathrm{SVR})$$

MAP=CO×systemic vascular resistance(SVR)

HR is controlled by the autonomic nervous system. SV, or the volume of blood ejected during systole, depends on preload, afterload, and contractility.[11] As defined by the Frank-Starling mechanism, the ability of the heart to alter the force of contraction depends on changes in preload. As myocardial sarcomere length is stretched, the number of cross-bridges between thick and thin myofilaments increases, resulting in an increase in the force of contraction. The length of the sarcomere is determined primarily by the volume of blood in the ventricle; therefore, left ventricular end-diastolic volume (LVEDV) is the primary determinant of preload. In normal hearts, the preload response is the primary compensatory mechanism such that a small increase in end-diastolic volume results in a large increase in CO. Because of the relationship between pressure and volume in the heart, left ventricular end-diastolic pressure (LVEDP) is often used in the clinical setting to estimate preload. The hemodynamic measurement used to clinically estimate LVEDP is the pulmonary capillary wedge pressure (PCWP) also known as the pulmonary artery occlusion pressure (PAOP). Afterload is a more complex physiologic concept that can be viewed pragmatically as the sum of forces preventing the active forward ejection of blood by the ventricle. Major components of afterload are ejection impedance, wall tension, and regional wall geometry. In patients with left ventricular systolic dysfunction, an inverse relationship exists between afterload (estimated clinically by SVR) and SV such that increasing afterload causes a decrease in SV (Fig. 36-1). Contractility is the intrinsic property of cardiac muscle describing fiber shortening and tension development.

FIGURE 36-1

Relationship between stroke volume and systemic vascular resistance. In an individual with normal left ventricular (LV) function, increasing systemic vascular resistance has little effect on stroke volume. As the extent of LV dysfunction increases, the negative, inverse relationship between stroke volume and systemic vascular resistance becomes more important (B to A).

Heart Failure with Preserved Ejection Fraction

②This disorder can be defined as a condition in which myocardial relaxation and filling are impaired and incomplete. The ventricle is unable to accept an adequate volume of blood from the venous system, does not fill at low pressure, and/or is unable to maintain normal SV. In its most severe form, HFpEF results in overt symptoms of HF. In modest HFpEF, symptoms of dyspnea and fatigue occur only during stress or activity, when HR and end-diastolic volume increase. In its mildest form, HFpEF can be manifested as a slow or delayed pattern of relaxation and filling with little or no elevation in diastolic pressure and few or no cardiac symptoms. The congestive symptoms that occur with HFpEF are a manifestation of increased pulmonary venous pressures. HFpEF is caused by impaired myocardial relaxation and/or increased diastolic stiffness. When HF is caused by a predominant abnormality in diastolic function, the ventricular chamber is not enlarged, and EF may be normal or even elevated.[12] Figure 36-2 shows the pressure-volume relationship in a patient with normal versus abnormal diastolic function. The changes in the myocardium are associated with a shift upward and to the left of the pressure-volume curve so that for any increase in LV volume, diastolic pressure rises to a much greater level than normally would occur. Clinically, patients present with reduced exercise tolerance and dyspnea when they have elevated LV diastolic pressures. Patients with HFpEF have a predominant abnormality in diastolic function, whereas patients with HFrEF have a predominant abnormality in the systolic function of the LV.

FIGURE 36-2

Diastolic pressure-volume relationship in a normal patient (right trace) and a patient with diastolic dysfunction (left trace).

HFpEF may represent a collection of syndromes because there is significant variability in morphology and functional presentation.[13] Some feel that a systemic inflammatory state and microvascular endothelial dysfunction play a role.[9] Although CAD is a common comorbidity, HF symptoms are often disproportionate to the severity of coronary artery disease. Obesity, HTN, and diabetes are proinflammatory and are frequent comorbidities in patients with HFpEF. During physical exertion, CO increases through integrated enhancements in venous return, contractility, HR, and peripheral vasodilation. The vasodilation that normally occurs during exercise is impaired in HFpEF.[13] Pulmonary HTN is also a common finding. Abnormalities in each of these components of normal exercise reserve function have been identified in HFpEF and all may contribute to pathophysiology in individual patients.[9,12]

Heart Failure with Reduced Ejection Fraction

③HFrEF is a progressive disorder initiated by any event that impairs the ability of the heart to contract and sometimes relax resulting in a decrease in CO. The index event may have an acute onset, as with MI, or the onset may be slow, as with long-standing HTN. Regardless of the index event, a decrease in CO results in the activation of compensatory responses to maintain circulation.[11,14] These compensatory responses include: (a) tachycardia and increased contractility through sympathetic nervous system (SNS) activation, (b) the Frank-Starling mechanism, whereby an increase in preload results in an increase in SV, (c) vasoconstriction, and (d) ventricular hypertrophy and remodeling. Compensatory responses evolved to provide short-term support to maintain circulatory homeostasis after acute reductions in BP or renal perfusion. However, the persistent decline in CO in HF triggers long-term activation of these compensatory responses resulting in the complex functional, structural, biochemical, and molecular changes important for the development and progression of HF. The beneficial and detrimental effects of these compensatory responses are described below and are summarized in Table 36-3.

TABLE 36-3

Beneficial and Detrimental Effects of the Compensatory Responses in Heart

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through Na^+ and water retention)	Optimizes stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2
Vasoconstriction	Maintains BP in face of reduced CO Shunts blood from nonessential organs to brain and heart	Increased MVO_2 Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Helps maintain CO	Increased MVO_2 Shortened diastolic filling time β_1-receptor downregulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias Increased risk of myocardial cell death
Ventricular hypertrophy and remodeling	Helps maintain CO Reduces myocardial wall stress Decreases MVO_2	Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk Fibrosis

BP, blood pressure; CO, cardiac output; MVO_2, myocardial oxygen demand; SNS, sympathetic nervous system.

Tachycardia and Increased Contractility

The increase in HR and contractility that rapidly occurs in response to a drop in CO is primarily due to the release of norepinephrine (NE) from adrenergic nerve terminals, although parasympathetic nervous system activity is also diminished.[14] Loss of atrial contribution to ventricular filling also can occur (atrial fibrillation, ventricular tachycardia), reducing ventricular performance even more. Because ionized calcium is sequestered into the sarcoplasmic reticulum and pumped out of the cell during diastole, the shortened diastolic time with increases in HR also results in a higher average intracellular calcium concentration during diastole, increasing actin-myosin interaction, augmenting the active resistance to fibril stretch, and reducing lusitropy. Conversely, the higher average calcium concentration translates into greater filament interaction during systole, generating more tension.[11] Increasing HR also increases myocardial oxygen demand. If ischemia is induced or worsened, both diastolic and systolic functions may become impaired, and SV can drop precipitously.

Fluid Retention and Increased Preload

Augmentation of preload is another compensatory response that is rapidly activated in response to decreased CO. Renal perfusion in HF is reduced due to both depressed CO and redistribution of blood away from nonvital organs. The kidney interprets the reduced perfusion as an ineffective blood volume, resulting in activation of the renin-angiotensin-aldosterone system (RAAS) in an attempt to maintain BP and increase renal sodium and water retention. Reduced renal perfusion and increased sympathetic tone also stimulate renin release from juxtaglomerular cells in the kidney. As shown in Fig. 36-3, renin is responsible for the conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II may also be generated via non–ACE-dependent pathways. Angiotensin II stimulates aldosterone release from the adrenal gland, thereby providing an additional mechanism for renal sodium and water retention. As intravascular volume increases secondary to sodium and water retention, left ventricular volume and pressure (preload) increase, sarcomeres are stretched, and the force of contraction is enhanced.[11] While the preload response is the primary compensatory mechanism in normal hearts, the chronically failing heart usually has exhausted its preload reserve.[11] As shown in Fig. 36-4, increases in preload will increase SV only to a certain point. Once the flat portion of the curve is reached, further increases in preload will only lead to pulmonary or systemic congestion, a detrimental result.[11] Figure 36-4 also shows that the curve is flatter in patients with left ventricular dysfunction. Consequently, a given increase in preload in a patient with HF will produce a smaller incremental increase in SV than in an individual with normal ventricular function.

FIGURE 36-3

Physiology of the renin-angiotensin-aldosterone system. Renin produces angiotensin I from angiotensinogen. Angiotensin I is cleaved to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II has a number of physiologic actions that are detrimental in HF. Note that angiotensin II can be produced in a number of tissues, including the heart, independent of ACE activity. ACE is also responsible for the breakdown of bradykinin. Inhibition of ACE results in the accumulation of bradykinin that, in turn, enhances the production of vasodilatory prostaglandins.

Vasoconstriction and Increased Afterload

Vasoconstriction occurs in patients with HFrEF to help redistribute blood flow away from nonessential organs to coronary and cerebral circulations to support BP, which may be reduced secondary to a decrease in CO (MAP = CO × SVR).[11] A number of neurohormones likely contribute to the vasoconstriction, including NE, angiotensin II, endothelin-1 (ET-1), neuropeptide Y, urotensin II, and arginine vasopressin (AVP).[11,14] Vasoconstriction impedes forward ejection of blood from the ventricle, further depressing CO and heightening the compensatory responses. The failing ventricle is exquisitely sensitive to changes in afterload (Fig. 36-1). Thus, increases in afterload often potentiate a vicious cycle of continued worsening and downward spiraling of the HF state.

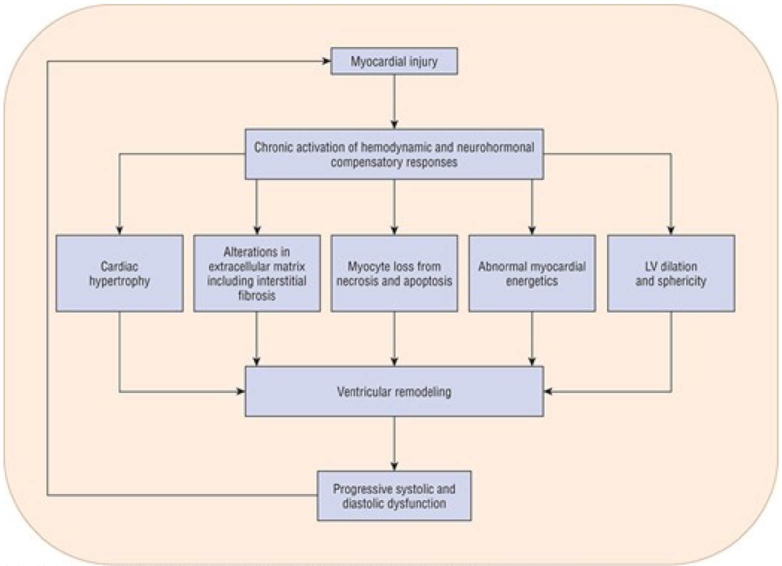
Ventricular Hypertrophy and Remodeling

③While the signs and symptoms of HF are closely associated with the items described above, the progression of HF appears to be independent of the patient’s hemodynamic status. It is now recognized that left ventricular hypertrophy and remodeling are key components in the pathogenesis of progressive myocardial failure.[11] *Ventricular hypertrophy* is a term used to describe an increase in ventricular muscle mass. *Cardiac or ventricular remodeling* is a broader term describing changes in both myocardial cells and the extracellular matrix that result in changes in the size, shape, structure, and function of the heart.[15] These progressive changes in ventricular structure and function ultimately result in a change in the shape of the left ventricle from an ellipse to a sphere. This change in ventricular size and shape serves to further depress the mechanical performance of the heart, increase regurgitant flow through the mitral valve, and, in turn, fuel the continued progression of remodeling. Ventricular hypertrophy and remodeling can occur in association with any condition that causes myocardial injury.[15] The onset of the remodeling process precedes the development of HF symptoms.

Cardiac remodeling is a complex process that affects the heart at the molecular and cellular levels.[11,15] Key elements in the process are shown in Fig. 36-5. Collectively, these events result in progressive changes in myocardial structure and function such as cardiac hypertrophy, myocyte loss, and alterations in the extracellular matrix. The progression of the remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, results in further myocardial injury, perpetuating the remodeling process and the decline in left ventricular performance. Angiotensin II, NE, ET, aldosterone, vasopressin, and numerous inflammatory cytokines, as well as substances under investigation, that are activated both systemically and locally in the heart and vasculature play an important role in initiating the signal transduction cascade responsible for ventricular remodeling. Although these mediators produce harmful effects on the heart, their increased circulating and tissue concentrations are also toxic to other organs and serve as an important reminder that HF is a systemic as well as a cardiac disorder.[11,14,15]

FIGURE 36-5

Key components of the pathophysiology of cardiac remodeling. Myocardial injury (eg, myocardial infarction) results in the activation of a number of hemodynamic and neurohormonal compensatory responses in an attempt to maintain circulatory homeostasis. Chronic activation of the neurohormonal systems results in a cascade of events that affect the myocardium at the molecular and cellular levels. These events lead to the changes in ventricular size, shape, structure, and function known as ventricular remodeling. The alterations in ventricular function result in further deterioration in cardiac systolic and diastolic functions that further promotes the remodeling process.



Myocardial injury
Chronic activation of hemodynamic and neurohormonal compensatory responses
Cardiac hypertrophy
Alterations in extracellular matrix including interstitial fibrosis
Myocyte loss from necrosis and apoptosis
Abnormal myocardial energetics
LV dilation and sphericity
Ventricular remodeling
Progressive systolic and diastolic dysfunction

Pressure overload (and probably hormonal activation) associated with HTN produces concentric hypertrophy (increase in the ventricular wall thickness without chamber enlargement), which is often found in HFpEF.[12] Conversely, eccentric left ventricular hypertrophy (myocyte lengthening with increased chamber size with minimal increase in wall thickness) characterizes the hypertrophy seen in patients with systolic dysfunction or previous MI. As the myocytes undergo change, so do various components of the extracellular matrix. For example, collagen degradation may lead to myocyte slippage, fibroblast proliferation, and increased fibrillar collagen synthesis, resulting in fibrosis and stiffening of the entire myocardium. Thus, a number of important ventricular changes that occur with remodeling include alterations in the geometry of the heart from an elliptical to a spherical shape, increases in ventricular mass (from myocyte hypertrophy), and changes in ventricular composition (especially the extracellular matrix) and volumes, all of which contribute to the impaired cardiac function. If the cardiac injury is acute (eg, MI), the ventricular remodeling process begins immediately. However, it is the progressive nature of this process that results in the continual worsening of the HF state, and thus is now the major focus for the identification of new therapeutic targets. In fact, HF pharmacotherapy associated with decreased mortality, and/or slowing the progression of the disease, produce these effects largely by slowing or reversing ventricular remodeling, a process often referred to as *reverse remodeling*.

Amyloid Cardiomyopathy

Amyloidosis is an uncommon multisystem disorder in which protein-based infiltrates deposit in tissues including the heart, kidneys, nerves, liver, lungs, and bowel leading to organ dysfunction and death. The vast majority of cardiac amyloidosis is caused by one of two proteins, light chains or transthyretin, resulting in distinct pathophysiology. While the two primary types of amyloidosis, immunoglobulin light chain (AL) and transthyretin (ATTR) are considered rare, ATTR amyloidosis is found in as many as 25% of adults older than 85 years on autopsy. Both forms of amyloidosis are underdiagnosed. Overall, 25% of patients with AL amyloidosis die within 6 months of diagnosis and 25% of patients with ATTR amyloidosis die within 24 months of diagnosis.

Cardiac amyloidosis occurs with the deposition of abnormal proteins into the extracellular space in the myocardium. Heart involvement may result in HF, more commonly HFpEF. Approximately 30 proteins are associated with amyloid cardiomyopathy; however, the most common is transthyretin (TTR). The DNA coding sequence for misfolded TTR can be inherited, causing the proteins to easily disassociate (hereditary type). ATTR cardiomyopathy is under-recognized and may be present in up to 15% of older adults with HF. Most cases of cardiac amyloidosis are not inherited but rather related to the aging process. The non-hereditary type (wild-type) is mostly observed in patients older than 60 years. Progressive HF, complicated by arrhythmias and conduction disturbances, may be part of the natural history of the disorder.[16]

Recent advances in standard chemotherapy to treat AL amyloidosis have markedly improved patient outcomes such that auto-stem-cell transplant is now only rarely indicated. ATTR-CM was treated only by cardiac transplantation. However, there are now three therapies approved for managing ATTR amyloidosis, depending on the clinical phenotype.[17–19]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the most common genetic disorder of the heart, occurring in one of every 200 to 500 persons. It is characterized by the presence of increased left ventricular (LV) wall thickness that is typically severe, asymmetric, and primarily affects the interventricular septum often resulting in obstruction of the left ventricular outflow tract. In up to 60% of adults with HCM, this disease is inherited in an autosomal dominant pattern, associated with mutations in genes encoding proteins of thick and thin myofilament contractile components of the cardiac sarcomere. HCM often remains clinically silent and is the most common cause of sudden death in athletes. Fortunately, pharmacologic, electrical, and surgical interventions have reduced mortality to 0.5% per year. Assessment of the risk of sudden cardiac death (SCD) is of paramount importance since sudden death is considered the main cause of death in younger patients with HCM. Genetic testing is increasingly being applied to patients who meet diagnostic criteria for HCM in order to identify the causative mutation for the disease and to determine the genetic predisposition of asymptomatic relatives. Typical symptoms of HCM include dyspnea, chest pain, palpitations, and syncope. Treatment is aimed at the improvement of symptoms, exercise capacity, and functional status. While pharmacological therapy is first-line, patients may experience symptoms refractory to medications, primarily related to left ventricular outflow obstruction, and surgical or other interventions may be needed.[20]

Neurohormonal Model of Heart Failure

②③ The current paradigm used to describe HF pathogenesis is the *neurohormonal model*.[11] This model recognizes an initiating event (eg, MI, long-standing HTN) that leads to decreased CO and begins the "HF state." The problem then moves beyond the heart, and it becomes a systemic disease whose progression is mediated largely by neurohormones and autocrine/paracrine factors that drive myocyte injury, oxidative stress, inflammation, and extracellular matrix remodeling. While the former paradigms still guide us to some extent in the symptomatic management of the disease (eg, diuretics), it is this latter paradigm that helps us understand disease progression and, more importantly, the ways to slow disease progression. In the sections that follow, key neurohormones and autocrine/paracrine factors, collectively termed biomarkers, are described with respect to their role in HF and its progression. The benefits of current and investigational drug therapies can be better understood through a solid understanding of the neurohormones they regulate. Although the neurohormonal model provides a logical framework for our current understanding of HF progression and the role of various medications in attenuating this progression, it must be emphasized that this model does not completely explain HF progression.

Angiotensin II

Of the neurohormones and autocrine/paracrine factors that play an important role in HFrEF pathophysiology, angiotensin II is probably the best understood.[11,21] Angiotensin II has multiple actions that contribute to its detrimental effects. It is a potent vasoconstrictor mediated by binding to the angiotensin type 1 (AT1) receptor in the vasculature, and it also causes a release of AVP and ET-1. Angiotensin II facilitates the release of NE from adrenergic nerve terminals, heightening SNS activation. It promotes sodium retention through direct effects on the renal tubules and by stimulating aldosterone release. Its vasoconstriction of the efferent glomerular arteriole helps to maintain renal perfusion pressure in patients with severe HF or impaired renal function. Finally, angiotensin II and many of the neurohormones released in response to angiotensin II play central roles in stimulating ventricular hypertrophy, remodeling, myocyte apoptosis, oxidative stress, inflammation, and alterations in the myocardial extracellular matrix. Clinical trials showing that attenuating angiotensin II-mediated effects with ACE inhibitors or ARBs improve hemodynamics, symptoms, hospitalizations, and survival highlight the importance of angiotensin II in HF pathophysiology.[22]

Norepinephrine

NE plays a central role in tachycardia, vasoconstriction, and increased contractility and plasma renin activity in HFrEF.[14] Plasma NE concentrations are elevated in correlation with the degree of HF, and patients with the highest plasma NE concentrations have the poorest prognosis.[11] Excessive SNS activation causes β_1-receptor downregulation with a subsequent loss of sensitivity to receptor stimulation. Excess catecholamines increase the risk of arrhythmias and can cause myocardial cell loss by stimulating both necrosis and apoptosis. Finally, NE contributes to ventricular hypertrophy and remodeling. The beneficial effects of β-blockers on outcomes in patients with HFrEF support the critical role of sympathetic nervous system activation and NE in the pathophysiology of the HF state.[8,22]

Aldosterone

Aldosterone-mediated sodium retention and its key role in volume overload and edema have long been recognized as important components of the HF syndrome.[11] Circulating aldosterone is increased in HF due to stimulation of its synthesis and release from the adrenal cortex by angiotensin II and due to decreased hepatic clearance from reduced hepatic perfusion. The direct effects of aldosterone on the heart may be even more important than sodium retention in HF pathophysiology. Aldosterone produces interstitial cardiac fibrosis through increased collagen deposition in the extracellular matrix of the heart. By increasing the stiffness of the myocardium, cardiac fibrosis may decrease systolic function and impair diastolic function. Extra-adrenal production of aldosterone in the heart, kidneys, and vascular smooth muscle also contributes to the progressive nature of HF through target organ fibrosis and vascular remodeling. Induction of a systemic proinflammatory state, increased oxidative stress, wasting of soft tissues and bone, secondary hyperparathyroidism, and mineral/micronutrient dyshomeostasis are other important pathologic actions of aldosterone that directly contribute to ventricular remodeling and HF progression.[11,21] Clinical trials with the aldosterone antagonists spironolactone[23] and eplerenone[24,25] showing significant reductions in morbidity and mortality in patients with HFrEF provide compelling evidence of the important role of aldosterone in HFrEF initiation and progression. Although not studied as extensively as in HFrEF, aldosterone antagonists also show benefit in patients with HFpEF.[26,27]

Natriuretic Peptides

The natriuretic peptide family has three members, atrial natriuretic peptide, B-type natriuretic peptide (BNP), and C-type natriuretic peptide. Of these, BNP and its biologically related inactive peptide NT-proBNP are the most useful in the diagnosis and management of HF.[22,28] BNP and NT-proBNP, are synthesized and released from the ventricle in response to pressure or volume overload. BNP or NT-proBNP plasma concentrations are elevated in patients with HF, increasing natriuresis and diuresis and attenuating activation of the RAAS and SNS. A recent clinical trial showing that neprilysin-mediated inhibition of natriuretic peptide breakdown improves outcomes in patients with HFrEF supports the importance of these peptides in HF pathophysiology.[29]

The development of easily performed commercial assays for BNP and NT-proBNP resulted in widespread interest in the role of these peptides as a biomarker for prognostic, diagnostic, and therapeutic use. In patients with chronic HFrEF, the degree of elevation in BNP concentrations is closely associated with poor outcomes.[28] Elevation of natriuretic peptide plasma concentrations now plays a key role in establishing the diagnosis of HF.[22] Clinicians should be aware that many cardiovascular and non-cardiovascular co-morbidities (eg, pulmonary embolism, pulmonary hypertension) as well as sex, race/ethnicity, and age may also affect natriuretic peptide levels.[22] In addition, obesity is associated with lower levels of BNP and NT-proBNP, and thus, diagnostic sensitivity in morbidly obese patients is reduced. The most well-established clinical application of BNP testing is in the urgent care setting where the BNP or NT-proBNP assay is useful when combined with clinical evaluation for differentiating dyspnea secondary to either HFrEF or HFpEF from other causes. In patients with either chronic or acute/hospitalized HF, measurements of BNP or NT-proBNP also have utility for risk stratification and prognosis.[28]

Studies evaluating the role of serial BNP measurement to guide drug therapy have not shown consistent improvement in long-term outcomes compared with standard medical therapy, particularly in patients with HFpEF.[28] Guidelines reflect this uncertainty and do not support the routine use of serial BNP measurement in chronic HF management.[28,30] Measurement of BNP should not preclude good clinical judgment and an individualized approach to each patient is imperative.

Other Factors

AVP is a pituitary peptide hormone that regulates renal water excretion and plasma osmolality.[11] Plasma concentrations of AVP are elevated in patients with HF, supporting its role in the pathophysiology of this disorder. The physiologic effects of AVP are mediated through the V_{1a}, V_{1b}, and V_2 receptors.

Stimulation of these receptors by increased circulating AVP results in several maladaptive responses including: (a) increased renal free water reabsorption in the face of plasma hypoosmolality resulting in volume overload and hyponatremia; (b) increased arterial vasoconstriction that contributes to reduced CO; and (c) stimulation of remodeling by cardiac hypertrophy and extracellular matrix collagen deposition. Although the AVP antagonists tolvaptan and conivaptan improve acute symptoms and increase serum sodium and urine output without affecting HR, BP, renal function, or other electrolytes, no improvements in morbidity and mortality were seen in clinical trials.[31]

The sodium-glucose-cotransporter-2 (SGLT2) is highly expressed in the renal proximal tubule and is responsible for reabsorbing more than 90% of filtered glucose that is coupled with Na^+ ions.[32] The SGLT2 inhibitors (eg, empagliflozin, dapagliflozin) lower blood glucose by increasing urinary glucose (and sodium) excretion resulting in diuresis and natriuresis. Clinical trials reported that these agents also reduce the risk of cardiovascular events in patients with HF, including hospitalizations, even in patients without diabetes, suggesting that mechanism(s) other than simply lowering blood glucose are important.[33] Although the exact beneficial mechanisms remain uncertain, these agents reduce inflammation, oxidative stress, and sympathetic nervous system activity as well as improve cardiac remodeling and myocardial energetics.[32,33] The impressive outcomes with these medications in patients with HF further support the notion of HF as a disorder driven by multiple systemic mechanisms.

Factors Precipitating/Exacerbating Heart Failure

Although significant advances have been made in treatment, symptom exacerbation, to the point that hospitalization is required, is a common and growing problem in patients with chronic HF. Hospitalization for HF exacerbation consumes large amounts of healthcare dollars and significantly impairs the patient’s quality of life. Thus, there is great interest in identifying and then remedying factors that increase the risk of decompensation. Appropriate therapy can often maintain patients in a “compensated” state, indicating that they are relatively symptom-free. However, there are many aggravating or precipitating factors that may cause a previously compensated patient to develop worsened symptoms necessitating hospitalization. Often, these precipitating factors are reversible or treatable, thus thorough evaluation for their presence is imperative.

Cardiac events are a frequent cause of worsening HF.[34] Myocardial ischemia and infarction are potentially reversible causes that must be carefully considered since nearly 70% of patients with HF have coronary artery disease. Revascularization should be considered in eligible patients. Atrial fibrillation is a common comorbidity in patients with HF and is associated with increased morbidity and mortality.[35] Control of ventricular response, maintenance of sinus rhythm in appropriate patients, and prevention of thromboembolism are important elements in the treatment of patients with concomitant HF and atrial fibrillation. Uncontrolled HTN is also an important contributing factor and should be treated according to current guidelines.[36]

Noncardiac events are also associated with HF decompensation. Pulmonary infections frequently cause worsening HF. Many of these events would be preventable with the more widespread use of the pneumococcal and influenza vaccines. Pulmonary embolus, diabetes, chronic kidney disease, hypothyroidism, and hyperthyroidism should also be considered.

Nonadherence with prescribed HF medications or with dietary recommendations (eg, sodium intake and fluid restriction) is also a common cause of HF exacerbation.[34] Polypharmacy is common in patients with HF.[37] Thus, nonadherence is an important contributor to poor outcomes and socioeconomically disadvantaged patients appear to be disproportionately affected.

Many drugs can precipitate or exacerbate HF by one or more of the following mechanisms: (a) negative inotropic effects; (b) direct cardiotoxicity; or (c) increased sodium and/or water retention (Table 36-4).[38] Agents with negative inotropic effects are primarily a concern in patients with HFrEF. Nonsteroidal anti-inflammatory drugs (NSAIDs) are increasingly recognized for their ability to exacerbate HF and increase the risk of hospitalization and mortality through volume retention, decreased renal function, and increased BP.[38] The ability of numerous antineoplastic agents to cause or worsen HF is increasingly recognized.[39,40]

TABLE 36-4

Selected Drugs That May Precipitate or Exacerbate Heart Failure

Negative inotropic effect Antiarrhythmics (disopyramide, dronedarone, flecainide, propafenone, sotalol) β-Blockers (eg, propranolol, metoprolol, carvedilol) Calcium channel blockers—nondihydropyridine type (verapamil, diltiazem) Itraconazole
Cardiotoxic Alkylating agents (eg, cyclophosphamide, ifosfamide, melphalan) Amphetamines (eg, cocaine, methamphetamine) Anthracyclines (eg, doxorubicin, daunorubicin, epirubicin, idarubicin) Antiarrhythmics (eg, disopyramide, dronedarone, flecainide, propafenone, sotalol) Antimetabolites (eg, fluorouracil, capecitabine, fludarabine, decitabine) Antimicrotubules (eg, docetaxel, paclitaxel) BCR-ABL inhibitors (eg, bosutinib, dastinib, imatinib, ponatinib) BRAF inhibitors (eg, dabrafenib) Carbamazepine Chimeric antigen receptor (CAR) T-cell therapy (eg, tisagenlecleucel, axicabtageneciloleucel) Daunomycin Ethanol Hormonal therapy (eg, aplalutamide, bicalutamide, darolutamide, nilutamide) Human epidermal growth factor receptor (HER/EGFR) inhibitors (eg, lapatinib, osimertinib) Human epidermal growth factor receptor 2 (HER2) inhibitors (eg, pertuzamab, trastuzumab) Immune checkpoint inhibitors (eg, nivolumab, ipilimumab, pembrolizumab) Immunomodulators (eg, lenalidomide, pomalidomide, thalidomide) MEK inhibitors (eg, binimetinib, cobimetinib, trametinib) Mitomycin Mitoxantrone Mitomycin Vascular endothelial growth factor (VEGF) inhibitors (eg, axitinib. bevacizumab, cabazantobinib, lenvatinib, pazopanib, sorafenib, sunitinib, vandetanib Miscellaneous (eg, entrectinib, fedratinib, ripretinib, tretinoin)
Sodium and water retention Androgens and estrogens Cyclooxygenase-2 (COX-2) inhibitors Rosiglitazone and pioglitazone Glucocorticoids Nonsteroidal anti-inflammatory drugs (NSAIDs) Pioglitazone and rosiglitazone Salicylates (high dose) Sodium-containing drugs (eg, carbenicillin disodium, ticarcillin disodium)
Uncertain mechanism Dipeptidyl peptidase-4 (DPP-4) inhibitors (eg, saxagliptin) TNF-α inhibitors (eg, adalimumab, infliximab, etanercept)

Many of the precipitating factors for HF are preventable, particularly through appropriate healthcare professional intervention. First and foremost, multidisciplinary teams should work collaboratively to identify and address such factors. Given medications are often a precipitating factor, engaging a pharmacist in HF care is recommended to assist with identifying inadequate HF therapy, detecting medication nonadherence, and avoiding drug-drug interactions or other medication-related causes of HF.[41,42] A careful medication history is an important aspect of evaluating the cause(s) of HF exacerbation as many are amenable to pharmacist intervention. Attention to these factors can contribute to reducing the risk of adverse cardiovascular outcomes and improving the patient's quality of life.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Heart Failure

Symptoms

Common

- Dyspnea, particularly on exertion
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Fatigue
- Swollen ankles of other parts of the body
- Bendopnea

Less Common

- Cough
- Wheezing
- Nocturia
- Anorexia, poor appetite, early satiety
- Nausea
- Bloating
- Weight gain or loss
- Dizziness or syncope
- Depression
- Reduced cognitive function (especially in the elderly)

Signs

Specific for Heart Failure

- Jugular venous distention

- Cardiomegaly, lateral displacement of the apical impulse
- Hepatojugular reflux
- S_3 gallop
- Cheyne-Stokes respiration (advanced HF)

Less Specific for Heart Failure

- Peripheral edema (lower extremities, sacral, scrotal)
- Pulmonary rales
- Pulmonary edema
- Weight gain (>2 kg/week)
- Weight loss with muscle wasting/cachexia (advanced HF)
- Pleural effusion
- Tachycardia/irregular pulse
- Tachypnea
- Hepatomegaly/ascites
- Cool extremities
- Oliguria
- Narrow pulse pressure
- Cardiomegaly
- Peripheral edema
- Hepatomegaly
- Venous stasis changes

Laboratory tests

- BNP > 35 pg/mL (ng/L; 10 pmol/L) for ambulatory patients or > 100 pg/mL (ng/L; 29 pmol/L) for patients hospitalized or with decompensated HF
- NT-proBNP >125 pg/mL (ng/L; 15 pmol/L) for ambulatory patients or > 300 pg/mL (ng/L; 35 pmol/L) for patients hospitalized or with decompensated HF
- An electrocardiogram may be normal or it could show numerous abnormalities including acute ST-T wave changes from myocardial ischemia, atrial fibrillation, bradycardia, left ventricular hypertrophy
- Serum creatinine: It may be increased due to hypoperfusion. Preexisting renal dysfunction can contribute to volume overload.
- Complete blood count is useful to determine if HF is due to reduced oxygen-carrying capacity
- Chest x-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions

- Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction
- Hyponatremia: Serum sodium <130 mEq/L (mmol/L) is associated with reduced survival and may indicate worsening volume overload and/or disease progression

Data from Reference [1].

Signs and Symptoms

① The primary manifestations of both HFrEF and HFpEF are dyspnea and fatigue, which lead to exercise intolerance, and fluid overload, which can result in peripheral edema and pulmonary congestion.[34,43] The presence of these signs and symptoms may vary considerably from patient to patient such that some patients have dyspnea but no signs of fluid retention, whereas others may have marked volume overload with few complaints of dyspnea or fatigue. However, many patients have both dyspnea and volume overload. Clinicians should remember that symptom severity often does not correlate with the degree of LV dysfunction. Patients with a low LVEF (less than 20%-25% [0.20-0.25]) may be asymptomatic, whereas those with preserved LVEF may have significant symptoms. Symptoms can vary considerably over time in a given patient, even in the absence of changes in ventricular function or medications.

Systemic congestion is associated with a number of signs and symptoms. Jugular venous distension (JVD) is the simplest and most reliable sign of fluid overload. Examination of the right internal jugular vein with the patient at a 45° angle is the preferred method for assessing JVD. The presence of JVD more than 4 cm above the sternal angle suggests systemic venous congestion. In patients with mild systemic congestion, JVD may be absent at rest, but the application of pressure to the abdomen will cause an elevation of JVD (hepatojugular reflux).

Peripheral edema is a cardinal finding in HF. Edema usually occurs in dependent parts of the body and is often seen as ankle or pedal edema in ambulatory patients, although it may be manifested as sacral edema in bedridden patients. Adults typically have a 10-lb (4.5 kg) fluid weight gain before trace peripheral edema is evident; therefore, patients with acute decompensated HF may have no clinical evidence of systemic congestion except weight gain. Body weight is thus an excellent short-term endpoint for evaluating fluid status. Nonfluid weight gain and loss of muscle mass due to cardiac cachexia are potential confounders for long-term use of weight as a marker for fluid status. Hepatomegaly and ascites are other signs of systemic congestion.

Patients with HFrEF may exhibit signs and symptoms of low CO alone or in addition to volume overload. The primary complaint associated with hypoperfusion is fatigue. Objective indicators of low CO include worsening renal function, cool extremities, altered mental status, resting tachycardia, low systolic blood pressure, and narrow pulse pressure.

Diagnosis

No single test is available to confirm the diagnosis of HF—it is a clinical syndrome with current or prior signs and symptoms due to any cardiac structural and/or functional disorder corroborated by elevated plasma natriuretic peptide concentrations or objective evidence of pulmonary or systemic congestion from a cardiogenic cause.[1,43] Because HF can be caused or worsened by multiple cardiac and noncardiac disorders, some of which may be treatable or reversible, accurate diagnosis is essential for the development of therapeutic strategies. HF is often initially suspected in a patient based on symptoms. However, signs and symptoms lack sensitivity for diagnosing HF since they are frequently found with many other disorders. Even in patients with known HF, there is a poor correlation between the presence or severity of symptoms and the hemodynamic abnormality. With few exceptions, HFpEF cannot be distinguished from HFrEF on the basis of the history, physical examination, chest x-ray, and ECG alone.[9] Patients with HFpEF are often elderly, with multiple comorbidities.[9]

A complete history and physical examination targeted at identifying cardiac or noncardiac disorders or behaviors that may cause or hasten HF development or progression are essential in the initial patient evaluation. Careful medication history should also be obtained with a focus on the use of medications that can precipitate or exacerbate HF (Table 36-4).[38]

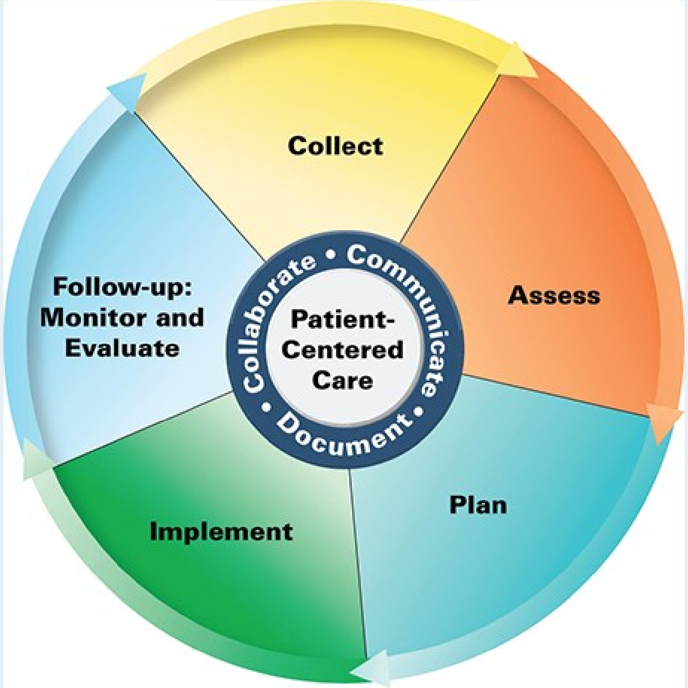
Particular attention should be paid to cardiovascular risk factors and to other disorders that can cause or exacerbate HF such as HTN, diabetes, atrial fibrillation, dyslipidemia, tobacco use, sleep-disordered breathing, iron deficiency, and thyroid disease. Since coronary artery disease is the cause of

HF in many patients, evaluation of the possibility of coronary disease is essential, especially in men. If coronary artery disease is detected, appropriate revascularization procedures may then be considered. The patient's volume status should be documented by assessing the body weight, JVD, and presence or absence of pulmonary congestion and peripheral edema. The biomarkers BNP or NT-proBNP are increased in most patients and their measurement is a key component of establishing the diagnosis of HF, particularly for differentiating dyspnea caused by HF from other causes.[1,30] The initial evaluation should include a complete blood count, serum electrolytes (including calcium and magnesium), assessment of renal and hepatic function, urinalysis, lipid profile, hemoglobin A1C, thyroid function tests, iron studies, chest x-ray, and 12-lead ECG.

Although the history, physical examination, and laboratory tests provide important insight into the underlying cause of HF, the echocardiogram is a standard test routinely used in the evaluation of the patient with HF. The echocardiogram is used to assess abnormalities in cardiac structure and function and should include evaluation of the pericardium, myocardium, and heart valves, and quantification of the LVEF to determine if systolic or diastolic dysfunction is present. Other imaging modalities may occasionally be used in conjunction with the echocardiogram including radionucleotide ventriculography, cardiac, computed tomography, and cardiac magnetic resonance.

PATIENT CARE PROCESS

Patient Care Process for Heart Failure



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

An illustration shows that patient-centered care includes collaboration, communication, and documentation. The actions associated with the care are collect, assess, plan, implement, and follow-up by monitoring and evaluating.

The processes of **Collect** and **Assess** are similar for patients with heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF) as are the processes of **Implement** and **Follow-up: Monitor and Evaluate**. In contrast, while the **Plan** process has many similarities between HFrEF and HFpEF, some important differences in the **Plan** are described below.

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use) and dietary habits including intake of sodium-containing foods and fluid

- Current medications including over-the-counter (OTC), herbal products, dietary supplements
- Etiology of heart failure (Table 36-1)
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, left ventricular ejection fraction, echocardiogram, chest x-ray
    - Labs including complete blood count, comprehensive metabolic panel (eg, serum Na, K, BUN, creatinine), urinalysis, liver function tests, thyroid-stimulating hormone, iron studies (serum ferritin and transferrin saturation) brain natriuretic peptide (BNP) or NT-pro-BNP, electrocardiogram (ECG)
    - Physical examination (eg, signs/symptoms of volume overload [see the "Clinical Presentation" box])

Assess

- Hemodynamic stability (eg, systolic BP <90 mm Hg, signs/symptoms of hypotension or poor perfusion)
- Presence of comorbidities (eg, coronary artery disease, hypertension, diabetes, atrial fibrillation)
- Presence of volume overload (eg, weight gain, rales, jugular vein distension, peripheral edema)
- Presence of exertional dyspnea, orthopnea, fatigue
- Emotional status (eg, presence of anxiety, depression)

Plan*

- HFrEF
    - Initiate and titrate guideline-directed medical therapy with ARNI/ACEI/ARB (ARNI preferred) + β-blocker + aldosterone antagonist + SGLT2 inhibitor (Fig. 36-6, Tables 36-7 and 36-9). Add diuretics if the patient is volume overloaded
    - Add additional drug therapy as indicated based on patient characteristics (eg, isosorbide/hydralazine, ivabradine, digoxin, vericiguat [Figs. 36-6 and 36-7, Tables 36-7 and 36-9])
- HFpEF
    - Initiate and titrate guideline-directed medical therapy with ARNI + aldosterone antagonist + SGLT2 inhibitor in select patients (Table 36-7–36-9). Add diuretics if the patient is volume overloaded.
- Monitoring parameters including efficacy (eg, shortness of breath, lower extremity edema, pulmonary congestion) and safety (eg, worsening renal function, hypotension, bradycardia [if prescribed β-blocker, ivabradine, or digoxin], hyperkalemia); follow-up frequency and timing
- Patient education (eg, the purpose of treatment, dietary and lifestyle modification, invasive procedures, drug-specific information, medication administration)
- Self-monitoring for HF symptoms (eg, daily weights, sodium and fluid intake)
- Referrals to other providers when appropriate (eg, HF specialist for consideration of advanced therapies [HFrEF], electrophysiologist for placement of ICD [HFrEF, secondary prevention of sudden cardiac death in select patients with HFpEF] and/or CRT [HFrEF], dietician)

Implement*

- Provide patient education regarding all elements of the treatment plan

- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, serum creatinine, electrolytes, vital signs, adherence assessment)

Follow-up: Monitor and Evaluate

- Resolution of HF signs and symptoms (eg, JVD, weight, shortness of breath)
- Evaluate the need for dose titration of GDMT and/or the initiation of additional therapies
- Presence of adverse effects (eg, serum creatinine, electrolytes, BP, HR)
- Patient adherence to treatment plan using multiple sources of information

[*] Collaborate with the patient, caregivers, and other healthcare professionals.

TREATMENT

Desired Outcomes

The goals of therapy in the management of chronic HF are to improve the patient's quality of life, relieve or reduce symptoms, prevent or minimize hospitalizations, slow progression of the disease, and prolong survival. Pharmacotherapy plays a key role in achieving these goals.[22,30] In addition, identification of risk factors for HF development and recognition of its progressive nature has led to increased emphasis on preventing the development of this disorder. In an attempt to standardize the definition of HF and provide clarity to clinicians and patients on optimal preventive and treatment approaches, an international group that included the Heart Failure Society of America, developed a staging system to emphasize that HF is a continuum and that not only recognizes the evolution and progression of the disorder but also emphasizes risk factor modification and preventive treatment strategies (Table 36-5).[1]

TABLE 36-5

Stages of Heart Failure

Stages	Definition
Stage A **At-risk for heart failure**	Patients at risk for HF but without current or prior symptoms or signs of HF and without structural, biomarker, or genetic markers of heart disease. ◦ Patients with HTN, CVD, DM, obesity, known exposure to cardiotoxins, family history of cardiomyopathy
Stage B **Pre-heart failure**	Patients without current or prior symptoms or signs of HF but evidence of *one* of the following: ◦ Structural heart disease: eg, LVH, chamber enlargement, wall motion abnormality, myocardial tissue abnormality, valvular heart disease ◦ Abnormal cardiac function: eg, reduced LV or RV systolic function, evidence of increased filling pressures or abnormal diastolic dysfunction ◦ Elevated natriuretic peptide levels or elevated cardiac troponin levels in the setting of exposure to cardiotoxins
Stage C **Heart failure**	Patients with current or prior symptoms and/or signs of HF caused by structural and/or cardiac abnormality. ◦ HF in remission *or* persistent HF
Stage D **Advanced heart failure**	Severe symptoms and/or signs of HF at rest, recurrent hospitalizations despite GDMT, refractory or intolerant to GDMT. ◦ Requiring advanced therapies such as consideration for transplant, mechanical circulatory support, or palliative care

CVD, cardiovascular disease; DM, diabetes; GDMT, guideline-directed medical therapy; HF, heart failure; HTN, hypertension; LV, left ventricle; LVH, left ventricular hypertrophy; RV, right ventricle.

Data from Reference [1].

The four stages of this system differ from the NYHA functional classification that classifies symptoms according to the clinician’s subjective evaluation and does not recognize preventive measures or the progression of the disorder (Table 36-6). For patients with symptomatic HF (stages C or D), symptoms can change frequently over a short period of time due to changes in medications, diet, intercurrent illnesses, etc. For example, a patient with Stage C HF with NYHA class IV symptoms such as marked volume overload could improve to class I or II with appropriate GDMT, yet they will remain categorized as Stage C.

TABLE 36-6

New York Heart Association Functional Classification

Functional Class	Physical Limitations and Symptoms
Class I	Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
Class II	Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
Class III	Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
Class IV	Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of congestive HF are present even at rest. With any physical activity, increased discomfort is experienced.

The general principles used to guide the treatment of HFrEF are based on numerous large, randomized, double-blind, multicenter trials. No such randomized trials had been performed in patients with HFpEF. Consequently, the guidelines for the management of HFpEF are based primarily on clinical investigations in relatively small groups of patients, clinical experience, and concepts based on the knowledge and understanding of the pathophysiology of the disease process. Treatment of HFpEF has been directed primarily at alleviation of congestion with diuretics, managing precipitating factors and co-morbid conditions (eg, ischemia, HTN, atrial fibrillation), and addressing underlying microvascular inflammation.[10] Previously, the typical therapies used for HFrEF have not shown a significant benefit for patients with HFpEF. However, more recent studies identified several agents that are also beneficial for HFpEF.

General Approach to Treatment

The complexity of the HF syndrome necessitates a comprehensive approach to management that includes accurate diagnosis, identification, and treatment of risk factors, elimination or minimization of precipitating factors, appropriate pharmacologic and nonpharmacologic therapy, and close monitoring and follow-up.

The first step in the management of chronic HF is to determine the classification of HF based upon LVEF and symptoms based upon NYHA functional class (see Tables 36-1 and 36-6) and/or any precipitating factors. Appropriate treatment of underlying disorders (eg, hyperthyroidism, valvular heart disease) may obviate the need for specific HF treatment. Revascularization or anti-ischemic therapy in patients with coronary disease may reduce HF symptoms. Drugs that aggravate HF (see Table 36-4) should be discontinued if possible.

Restriction of dietary sodium and fluid intake is an important lifestyle intervention for both HFrEF and HFpEF. Mild (<3 g/day) to moderate (<2 g/day) sodium restriction, in conjunction with daily measurement of weight, should be implemented to minimize volume retention and allow the use of lower and safer diuretic doses. Patients should avoid adding salt to prepared foods and eliminate foods high in sodium (eg, salt-cured meats, salted snack foods, pickles, soups, delicatessen meats, and processed foods). In patients with hyponatremia (serum Na <130 mEq/L [mmol/L]) or those with persistent volume retention despite high diuretic doses and sodium restriction, daily fluid intake should be limited to 2 L/day from all sources. However, both sodium and fluid restriction must be done with care in patients with HFpEF. Excessive restriction can lead to hypotension, a low-output state, and/or renal insufficiency. Daily weights may help assess volume status. Dietary and lifestyle factors that decrease the risk of development of CAD, HTN, diabetes, and obesity should be encouraged. Although guidelines indicate sodium restriction is reasonable to minimize congestion, proven benefits on clinical outcomes are lacking.

Other important general measures include patient and family counseling on the signs and symptoms of HF, detailed written instructions on the importance of appropriate medication use and compliance, activity level, diet, discharge medications, weight monitoring, continuity of care, and the need for close monitoring and follow-up to reinforce compliance and minimize the risk of HF exacerbations and subsequent hospitalization[22]

④ Treatment guidelines are organized around the four identified stages of HFrEF, and the recommendations are summarized in Fig. 36-6.[22,34] These figures address stages A-C with stage D discussed in greater detail in "Acute Decompensated Heart Failure," Chapter 37. While the guidelines primarily focus on HFrEF, discussions of HFpEF, acute decompensated HF, and management of patients with comorbid diseases often encountered in this population are included. Dosing recommendations for GDMT used to treat patients with HFrEF and HFpEF are provided in Table 36-7.

TABLE 36-7

Guideline Recommended Drug Therapies and Doses for HFrEF and HFpEF

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Loop Diuretics					
Furosemide	Lasix®	20-40 mg once or twice daily	20-160 mg once or twice daily	Cl_{cr} 20-50 mL/min (0.33-0.83 mL/s): 160 mg once or twice daily	Single doses exceeding those listed are unlikely to elicit additional response
				Cl_{cr} <20 mL/min (0.33 mL/s): 400 mg daily	
Bumetanide	Bumex®	0.5-1.0 mg once or twice daily	1-2 mg once or twice daily	Cl_{Cr} 20-50 mL/min (0.33-0.83 mL/s): 2 mg once or twice daily	Single doses exceeding those listed are unlikely to elicit additional response
				Cl_{cr} <20 mL/min (0.33 mL/s): 8-10 mg daily	
Torsemide	Demadex®	10-20 mg once daily	10-80 mg once daily	Cl_{Cr} 20-50 mL/min (0.33-0.83 mL/s): 40 mg once daily	Single doses exceeding those listed are unlikely to elicit additional response
				Cl_{cr} <20 mL/min (0.33 mL/s): 200 mg daily	
ACE Inhibitors					
Captopril	Capoten®	6.25 mg three times daily	50 mg three times daily[a]		
Enalapril	Vasotec®	2.5 mg twice daily	10-20 mg twice daily[a]		

Lisinopril	Zestril®, Prinivil®	2.5-5.0 mg once daily	20-40 mg once daily[a]		
Quinapril	Accupril®	5 mg twice daily	20-40 mg twice daily		
Ramipril	Altace®	1.25-2.5 mg once daily	10 mg once daily[a]		
Fosinopril	Monopril®	5-10 mg once daily	40 mg once daily		Undergoes both hepatic and renal elimination
Trandolapril	Mavik®	1.0 mg once daily	4 mg once daily[a]		Undergoes both hepatic and renal elimination
Perindopril	Aceon®	2 mg once daily	8-16 mg once daily		Undergoes both hepatic and renal elimination
Angiotensin Receptor Blockers					
Candesartan	Atacand®	4-8 mg once daily	32 mg once daily[a]		
Valsartan	Diovan®	20-40 mg twice daily	160 mg twice daily[a]		
Losartan	Cozaar®	25-50 mg once daily	150 mg once daily[a]		
Angiotensin Receptor Blocker/Neprilysin Inhibitor					
Sacubitril/valsartan	Entresto®	49/51 mg sacubitril/valsartan twice daily	97/103 mg sacubitril/valsartan twice daily[a]		For patients taking a low dose of or not taking an ACE inhibitor or ARB or if eGFR is <30 mL/min/1.73 m^2, the starting dose is 24/26-mg sacubitril/valsartan twice daily
Beta-blockers					
Bisoprolol	Zebeta®	1.25 mg once daily	10 mg once daily[a]		
Carvedilol	Coreg®	3.125 mg twice daily	25 mg twice daily[a]	Target dose for patients weighing >85 kg is 50 mg twice daily	Should be taken with food
Carvedilol phosphate	Coreg CR®	10 mg once daily	80 mg once daily		Should be taken with food
Metoprolol succinate CR/XL	Toprol-XL®	12.5-25 mg once daily	200 mg once daily[a]		
Aldosterone Antagonists					

Spironolactone	Aldactone®	eGFR >50 mL/min/1.73 m^2: 12.5-25 mg once daily	25-50 mg once daily[a]	eGFR 30-49 mL/min/1.73 m^2: 12.5 mg once daily or every other day	The risk of hyperkalemia increases if serum creatinine is >1.6 mg/dL (141 μmol/L). Avoid if baseline potassium is >5 mEq/L (mmol/L)
Eplerenone	Inspra®	eGFR >50 mL/min/1.73 m^2: 25 mg once daily	50 mg once daily[a]	eGFR 30-49 mL/min/1.73 m^2: 25 mg every other day	The risk of hyperkalemia increases if serum creatinine is >1.6 mg/dL (141 μmol/L). Avoid if baseline potassium is >5 mEq/L (mmol/L)
SGLT2 Inhibitors					
Dapagliflozin	Farxiga®	10 mg daily	10 mg daily	eGFR ≥ 30 mL/min/1.73 m^2	
Empagliflozin	Jardiance®	10 mg daily	10 mg daily	eGFR ≥ 20 mL/min/1.73 m^2	
Others					
Hydralazine-Isosorbide Dinitrate	Bidil®	Hydralazine 37.5 mg three times daily	Hydralazine 75 mg three times daily[a]		Indicated in conjunction with standard heart failure therapy in patients with HFrEF to improve survival and reduce hospitalizations in Black patients. Also an alternative if intolerance to ACEI/ARB/ARNI (e.g. angioedema).
Digoxin	Lanoxin®	Isosorbide dinitrate 20 mg three times daily	Isosorbide dinitrate 40 mg three times daily[a]	Reduce dose in elderly, patients with low lean body mass, and patients with impaired renal function	Indicated in conjunction with standard HF therapy in patients with HFrEF to improve survival and reduce hospitalizations in self-identified African-American patients. Also an alternative if intolerance to ACEI/ARB/ARNI (eg, angioedema).
		0.125-0.25 mg once daily	0.125-0.25 mg once daily		Indicated in conjunction with standard HF therapy in patients with HFrEF to improve symptoms and reduce hospitalizations. Target plasma concentration range is 0.5-0.9 ng/mL (μg/L; 0.6-1.2 nmol/L). Does not improve survival in patients with HFrEF
Ivabradine	Corlanor®	5 mg twice daily	5-7.5 mg twice daily	Avoid if resting heart rate <60 BPM before treatment	Indicated in conjunction with standard HF therapy in patients with HFrEF to reduce the risk of hospitalization in patients with HFrEF with a resting heart rate >70 BPM receiving maximally tolerated beta-blocker doses. Take with meals.
Vericiguat	Verquvo®	2.5 mg once daily	10 mg once daily		Indicated in conjunction with standard HF therapy in patients with HFrEF to improve CV survival and reduce HF hospitalization. Take with

					food.

[a] Regimens proven in large clinical trials to reduce mortality.

BPM, beats per minute; Cl_{cr}, creatinine clearance; CV, cardiovascular; eGFR, estimated glomerular filtration rate; HF, heart failure; HFrEF, heart failure with reduced ejection fraction.

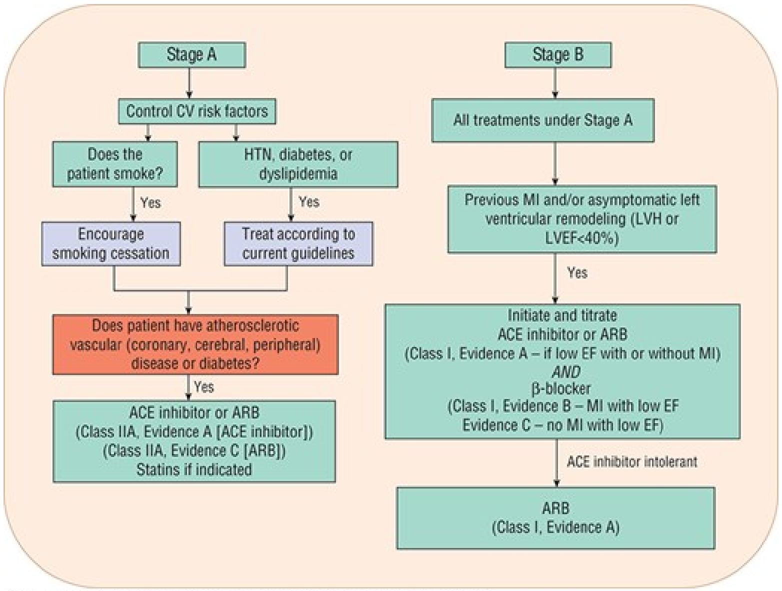
FIGURE 36-6

Guideline-directed treatment algorithm for patients with Stages A and B heart failure with reduced ejection fraction. *(Data from Reference* [22]*.)*



Stage A
Control CV risk factors
Does the patient smoke?
HTN, diabetes, or dyslipidemia
Yes
Yes
Encourage smoking cessation
Treat according to current guidelines
Does patient have atherosclerotic vascular (coronary, cerebral, peripheral) disease or diabetes?
Yes
ACE inhibitor or ARB (Class IIA, Evidence A [ACE inhibitor]) (Class IIA, Evidence C [ARB]) Statins if indicated
Stage B
All treatments under Stage A
Previous MI and/or asymptomatic left ventricular remodeling (LVH or LVEF<40%)
Yes
Initiate and titrate ACE inhibitor or ARB (Class I, Evidence A – if low EF with or without MI) AND β-blocker (Class I, Evidence B – MI with low EF Evidence C – no MI with low EF)
ACE inhibitor intolerant
ARB (Class I, Evidence A)

Less information guiding the treatment of HFpEF was available. This relative paucity of evidence is reflected in guidelines for the diagnosis and management of HFpEF published by the ACC/AHA/HFSA and the ESC.[30,44] In general, all three guidelines recommend treating comorbid conditions by controlling HR and BP, alleviating causes of myocardial ischemia, reducing volume, and restoring and maintaining sinus rhythm in patients with atrial fibrillation. Table 36-8 summarizes the therapeutic recommendations for HFpEF.

TABLE 36-8

Pharmacotherapy for Heart Failure with Preserved Ejection Fraction

Recommendations

- Systolic and diastolic blood pressure should be controlled in patients with HF*p*EF in accordance with published clinical practice guidelines to prevent morbidity.
- A loop of thiazide diuretic should be used for the relief of symptoms due to volume overload in patients with HF*p*EF.
- Coronary revascularization is reasonable in patients with CAD in whom symptoms (angina) or demonstrable myocardial ischemia is judged to be having an adverse effect on symptomatic HF*p*EF despite GDMT.
- Management of AF according to published clinical practice guidelines in patients with HF*p*EF is reasonable to improve symptomatic HF.
- The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure in patients with HF*p*EF.
- In selected patients with HF*p*EF (with EF ≥45% (0.45), elevated BNP levels or HF admission within 1 year, estimated glomerular filtration rate >30 mL/min (0.5 mL/s), creatinine <2.5 mg/dL [221 µmol/L], potassium <5.0 mEq/L [mmol/L]), aldosterone receptor antagonists might be considered to decrease hospitalizations.
- The use of ARBs might be considered to decrease hospitalizations for patients with HF*p*EF.

Data from Reference [30].

ACE, angiotensin-converting enzyme.

As the management of HF has become increasingly complex, disease management programs that include HF specialty clinics, home-based interventions, structured telephone support, and close patient follow-up are frequently used. Most are multidisciplinary and may include physicians, advanced practice nurses, dieticians, and pharmacists. In general, the programs focus on optimization of drug and non-drug therapy, patient and family education and counseling, exercise and dietary advice, intense follow-up by telephone or home visits, improving adherence to medications and lifestyle recommendations, encouragement of self-care, early recognition of and management of volume overload, and referral to palliative care when appropriate.[22] Such programs typically focus on patients with more severe HF who are at high risk for hospital admission. In general, multidisciplinary disease management programs improve quality of life and reduce HF and all-cause hospitalizations and costs, although these benefits are not consistently demonstrated in all studies.

Treatment of Stage A Heart Failure

Patients who are at-risk for HF are classified as Stage A.[1] These patients have no HF signs and symptoms or structural or biomarker evidence of heart disease but are at risk for developing HF because of the presence of risk factors (Fig. 36-6). The emphasis in these patients is on risk factor identification and modification to prevent the development of structural heart disease and subsequent HF. Commonly encountered risk factors include HTN, dyslipidemia, diabetes, obesity, metabolic syndrome, smoking, exposure to cardiotoxins, and coronary artery disease. Although each of these disorders individually increases risk, they frequently coexist in many patients and act synergistically to foster the development of both HFrEF and HFpEF.[3] Effective blood pressure control reduces the risk of developing HF by approximately 50%; thus, current HTN-treatment guidelines should be followed.[3,30,36] Obesity, diabetes, and metabolic syndrome also importantly contribute to the risk of developing HF.[3,45] Appropriate management of coronary disease and its associated risk factors are also important. Although treatment must be individualized, ACE inhibitors or ARBs and statins are recommended for HF prevention in select patients with atherosclerotic vascular disease or diabetes.[34] While not yet incorporated into guidelines addressing Stage A HF, sodium-glucose cotransporter type 2 (SGLT2) inhibitors should be strongly considered in patients with diabetes as these agents reduce the risks of adverse cardiovascular events and hospitalization for HF.[45,46]

Treatment of Stage B Heart Failure

Patients in Stage B, or pre-HF, have structural heart disease, abnormal cardiac function (eg, systolic and/or diastolic dysfunction), or increased natriuretic peptide plasma concentrations, but do not have current or prior HF symptoms.[1] This group includes patients with left ventricular hypertrophy, recent or remote MI, valvular disease, or LVEF < 40% (0.4). Treatment is targeted at minimizing additional injury and preventing or slowing the remodeling process. In addition to the treatment measures outlined in Stage A, all patients with an LVEF < 40% (0.4) should receive an ACE inhibitor or ARB and a β-blocker, especially if there is a history of MI.[34] While not yet incorporated into the guidelines for Stage B, an aldosterone antagonist should be used in patients post-MI if LVEF is less than 40% (0.4) or DM is present and an SGLT2 inhibitor considered in patients with DM to prevent HF development.[25,45,46]

Treatment of Stage C Heart Failure

Patients with structural heart disease and previous or current symptoms are classified in Stage C. Most patients with HFrEF in Stage C should be routinely treated with GDMT proven to improve morbidity and mortality (Fig. 36-6).[22] In select patients, hydralazine-isosorbide dinitrate (ISDN), loop diuretics, digoxin, ivabradine, and vericiguat may also be considered.[22] Nonpharmacologic therapy with devices such as an implantable cardioverter-defibrillator (ICD) or cardiac resynchronization therapy (CRT) with a biventricular pacemaker is also indicated in certain patients with HFrEF in Stage C (see the "Nonpharmacologic Therapy" section.[22]

Treatment of Stage D Heart Failure

Patients with advanced HF or classified as Stage D.[1] These patients experience persistent symptoms despite receiving maximally tolerated GDMT. This stage is often also referred to as refractory or end-stage HF. These patients often undergo recurrent hospitalizations or cannot be discharged from the hospital without special interventions, have a poor quality of life, and are at high risk for morbidity and mortality. Patients with advanced HFrEF should be considered for referral to HF management programs so that specialized therapies including mechanical circulatory support, continuous IV positive inotropic therapy, and cardiac transplantation can be considered in addition to standard treatments outlined in Stages A to C.[34,49] Unfortunately, these same advanced therapies are not beneficial for patients with HFpEF. For all patients with advanced HFrEF or HFpEF, discussions with the patient and family members regarding prognosis, patient priorities for minimizing symptoms versus prolonging survival, options for additional treatments, and end-of-life and hospice care should be initiated.[22] The approach to the treatment of patients with Stage D HF is discussed in more detail in Chapter 37.

Nonpharmacologic Therapy

Sudden cardiac death, primarily due to ventricular tachycardia and fibrillation, is responsible for 40% to 50% of the mortality in patients with HFrEF. Implantation of an ICD prevents sudden cardiac death and is an effective primary prevention strategy to reduce the risk of mortality in selected patients with HFrEF.[50] Current guidelines recommend the use of an ICD for primary prevention in patients receiving GDMT with NYHA class II-III symptoms and an LVEF <35% (0.35) that are expected to live for at least 1 year.[50] In patients with NYHA class I symptoms and an LVEF <30% (0.30), an ICD is also recommended for primary prevention if life expectancy exceeds 1 year.[50]

Delayed electrical activation of the left ventricle, characterized on the ECG by a QRS duration that exceeds 120 ms, occurs in approximately one-third of patients with moderate-to-severe HFrEF. Since the left and right ventricles normally activate simultaneously, this delay results in asynchronous contraction of the ventricles and contributes to the hemodynamic abnormalities of HF. Implantation of a specialized biventricular pacemaker, cardiac resynchronization therapy (CRT), to restore synchronous activation of the ventricles improves ventricular function and hemodynamics and is associated with reverse remodeling and increased LVEF. The use of CRT improves exercise capacity, symptoms, quality of life, hospitalizations, and mortality in patients with HRrEF.[34] Guidelines recommend CRT in patients receiving GDMT that have NYHA class II-III or ambulatory class IV symptoms and with a QRS duration >150 ms and LVEF <35% (0.35).[34] CRT can also be considered in selected patients with a QRS duration between 120 and 149 ms. Combined CRT and ICD devices are used if the patient meets the indications for both devices.

Wireless hemodynamic monitoring of pulmonary artery pressures remotely as a supplemental measurement of fluid status in patients at high risk for HF-related hospitalization is now possible.[51] The CardioMEMS™ implantable pulmonary artery sensor reduces the risk of HF hospitalization in selected patients.[52] In contrast, the usefulness of noninvasive telemonitoring or remote monitoring of physiological parameters (eg, patient activity, impedance, heart rate) via implanted electrical devices (ICDs or CRT-Ds) to improve clinical outcomes remains uncertain.

In patients with stage D HFrEF receiving GDMT, the use of mechanical circulatory support with a left ventricular assist device (LVAD) can be considered in certain patients.[34] Although the criteria for use of these devices continue to rapidly evolve, they are frequently used to bridge patients to cardiac transplant or as destination therapy in patients ineligible for transplant, and their use in these settings is associated with better survival and improved functional capacity.[34,53] Their use is covered in more detail in Chapter 37 (Acute Decompensated Heart Failure).

Pharmacologic Therapy

Pharmacologic Therapy for Stages B–D HFrEF

A treatment algorithm for the management of patients with Stages A or B HFrEF is shown in Fig. 36-6 and for Stage C HFrEF in Fig. 36-7. In general, patients with Stage B HFrEF should receive an ACE inhibitor or ARB, β-blocker, aldosterone antagonist, and an SGLT2 inhibitor.[34] Patients with Stage C HFrEF should receive combined therapy with an ARNI (preferred) or ACE inhibitor or ARB, β-blocker, aldosterone antagonist, and SGLT2 inhibitor.[22] The optimal sequence for initiating these four medication classes remains uncertain. However, there is growing interest in simultaneous initiation of low doses of each drug class due to the incremental and early benefits of these different medications on morbidity and mortality.[54,55] Given the demonstrated benefits of optimal GDMT on crucial outcomes and that large numbers of patients receive inadequate GDMT, strategies to improve the initiation and dose titration of these life-saving treatments are clearly needed.[56,57]

FIGURE 36-7

Guideline-directed treatment algorithm for patients with Stage C heart failure with reduced ejection fraction. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor; eGFR, estimated glomerular filtration rate; HFrEF, heart failure with reduced ejection fraction; HR, heart rate; K^+, potassium; NYHA, New York Heart Association; SGLT2, sodium-glucose cotransporter-2) *ACEI/ARB should only be considered in patients with contraindications, intolerance or inaccessibility to ARNI. A diuretic should be administered if there is evidence of fluid retention. Other therapies including the combination of hydralazine-nitrates, digoxin, ivabradine, or vericiguat can be considered in selected patients.[22] Drug dosing and monitoring are summarized in Tables 36-7 and 36-9.

TABLE 36-9

Drug Monitoring

Drug Class	Adverse Effect	Monitoring Parameters	Comments
Diuretics	Hypovolemia, hypotension, hyponatremia, hypokalemia, hypomagnesemia, hyperuricemia, renal dysfunction, thirst	BP, electrolytes, BUN, creatinine, glucose, uric acid, changes in weight, JVD	Dose should be adjusted based on volume status, renal function, electrolytes, and BP. Reassess these parameters 1-2 weeks after dose changes. Goal is lowest dose that maintains euvolemia.
ACE inhibitors	Angioedema, cough, hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis, history of angioedema, or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or increase in dose. Goal is target dose from clinical trials or highest tolerated.
ARBs	Hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or increase in dose. Use with caution in patients with a history of ACE inhibitor-associated angioedema. Goal is target dose from clinical trials or highest tolerated.
ARNI	Angioedema, hyperkalemia, hypotension, dizziness, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with a history of angioedema associated with ACE inhibitor or ARB therapy or in pregnancy. ACE inhibitors should be discontinued at least 36 hours before ARNI initiation. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or dose increase. Start with a low dose and double the dose every 2-4 weeks as tolerated based on BP, serum potassium, and renal function. Goal is target dose from clinical trials or highest tolerated.
β-blockers	Bradycardia, heart block, bronchospasm, hypotension, worsening HF	BP, HR, ECG, signs and symptoms of worsening HF, blood glucose	Start with low dose and titrate upward no more often than every 2 weeks as tolerated based on BP, HR, and symptoms. Goal is target dose from clinical trials or highest tolerated. Patients may feel worse before they feel better.
Aldosterone antagonists	Gynecomastia/breast tenderness/menstrual irregularities (spironolactone), hyperkalemia, worsening renal function	BP, electrolytes, BUN, and creatinine	Assess BP, BUN, creatinine, and electrolytes at baseline. Check potassium 3 days and 1 week after initiation and then monthly for the first 3 months. Change to eplerenone if gynecomastia develops with spironolactone.
SGLT2 inhibitors	Mycotic genital infections, volume depletion, acute kidney injury, or impairment of renal function, necrotizing fasciitis of the perineum (Fournier's gangrene), urosepsis or pyelonephritis, diabetic ketoacidosis	Volume status (weight, BP, hematocrit, electrolytes), BUN, and creatinine, blood glucose and HbA1c if diabetic	Contraindicated for patients on dialysis (per package insert), lactating (no data), or with type 1 diabetes (risk of euglycemic acidosis). Monitor volume status, especially if receiving concomitant diuretics. Benefit for HFrEF is regardless of presence of diabetes.

Hydralazine	Hypotension, headache, rash, arthralgia, lupus, tachycardia	BP, HR	
Nitrates	Hypotension, headache, lightheadedness	BP, HR	
Digoxin	GI and CNS adverse effects, brady- and tachyarrhythmias.	Electrolytes, BUN, creatinine, ECG, serum digoxin concentration	Target serum digoxin concentration 0.5-0.9 ng/mL (μg/L; 0.6-1.2 nmol/L)
Ivabradine	Bradycardia, hypertension, atrial fibrillation, luminous phenomena (phosphenes, transiently enhanced brightness in a portion of the visual field	BP, HR, ECG	Start with 5 mg twice daily and after 2 weeks adjust dose to achieve a resting HR 50-60 BPM. Only use in patients in sinus rhythm.
Vericiguat	Hypotension, anemia	BP, Hgb, Hct	

Pharmacologic Therapy for HFpEF

With a few notable exceptions, the drugs used to treat HFpEF are the same as those used to treat HFrEF. However, the rationale for their use, the pathophysiologic process that is being addressed by the drug, and the dosing regimen may be different. For example, β-blockers are recommended for the treatment of both HFrEF and HFpEF. However, in HFpEF, β-blockers should only be prescribed to those patients who have a comorbid condition that have an indication for β-blocker therapy. In HFpEF, ACE inhibitors, ARBs, and β-blockers have not demonstrated efficacy in the absence of other comorbid conditions such as HTN or myocardial infarction. Diuretics also are used in the treatment of both HFrEF and HFpEF. However, the doses of diuretics used to treat HFpEF are, in general, much lower than those used to treat HFrEF. Some drugs, however, are used to treat HFpEF, but not HFrEF. Calcium channel blockers such as diltiazem, amlodipine, and verapamil have little utility in the treatment of HFrEF and are often contraindicated as described in Table 36-4. In contrast, each of these drugs may be useful in the treatment of HFpEF when used for the treatment of HTN. ARNIs and SGLT2 inhibitors are beneficial in select patients with HFpEF. Drug dosing and monitoring for these agents is similar in HFrEF and HFpEF and are summarized in Tables 36-7 and 36-9.

While dozens of trials demonstrated the benefit of pharmacotherapy in patients with HFrEF, only a few recent studies demonstrated benefit in patients with HFpEF. Early trials led to ARBs and spironolactone being recommended in HFpEF patients to reduce hospitalization.[27,58] While most studies targeting the renin-angiotensin-aldosterone system have been disappointing, the PARAGON-HF trial led to sacubitril/valsartan being the first therapy approved in the United States to reduce cardiovascular mortality and hospitalizations in patients diagnosed with HF regardless of LVEF, with the greatest benefit evident in patients with LVEF below normal.[48] Shortly afterward, the EMPEROR-preserved Trial also demonstrated benefit with the SGLT2 inhibitor empagliflozin.[47] The results of these two pivotal HFpEF clinical trials are summarized in Table 36-10.

TABLE 36-10

Key Clinical Trials for HFpEF

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary Endpoint	Results
EMPEROR-Preserved (n = 5988)[47]	Empagliflozin vs placebo daily for a median follow-up of 26.2 months, in addition to usual therapy.	NYHA II-IV, EF > 40% (0.40), NT-proBNP > 300 pg/mL (ng/L; 35 pmol/L) (> 900 pg/mL [ng/L; 106 pmol/L] for patients with atrial fibrillation at baseline)	Composite of adjudicated CV death or hospitalization for HF	The primary outcome occurred in 13.8% of the empagliflozin group and 17.1% of the placebo group (HR 0.79, $P < 0.001$). Of the two composite endpoints, there was only a significant reduction, in the risk of hospitalization for heart failure.
PARAGON-HF[48] (n = 4,822)	Sacubitril/valsartan vs valsartan	NYHA class II-IV with EF>45% (0.45)	Composite of CV death and total HF hospitalization	No significant difference was found in the primary endpoint between treatment groups (rate ratio 0.87; 95% CI 0.75-1.01, P=0.06). A prespecified subgroup demonstrated benefit in patients with an EF in the lower part (45%- 57% [0.45-0.57]) of the range.

NYHA, New York Heart Association; EF, ejection fraction; CV, cardiovascular; HF, heart failure; HR, hazard ratio; CI, confidence interval.

ACE Inhibitors

5 For decades, ACE inhibitors have been a key component of the pharmacotherapy of patients with HFrEF.[22] By blocking the conversion of angiotensin I to angiotensin II by ACE, the production of angiotensin II and, in turn, aldosterone is decreased. This decrease in angiotensin II and aldosterone attenuates many of the deleterious effects of these neurohormones that drive HF initiation and progression. ACE inhibitors also inhibit the breakdown of bradykinin, which increases vasodilation and also leads to cough. The evidence that ACE inhibitors improve symptoms, slow disease progression, and decrease mortality in patients with HFrEF is unequivocal. As a result, prior guidelines recommend that all patients with HFrEF, regardless of whether or not symptoms are present, should receive ACE inhibitors to reduce morbidity and mortality, unless there are contraindications.[30,34] As described above, more recent evidence suggests that sacubitril/valsartan is preferred over ACE inhibitors (or ARBs) for HFrEF unless other circumstances (eg, affordability) are present in individual patients.

Numerous placebo-controlled clinical trials in both symptomatic and asymptomatic patients with reduced LVEF have documented the favorable effects of ACE inhibitor therapy on symptoms, HF progression, hospitalizations, and quality of life.[30,34] ACE inhibitors improve survival compared with placebo, and these benefits are maintained with continued therapy.[30,34] The benefits of ACE inhibitor therapy are independent of the etiology of HF (ischemic vs nonischemic) and are greatest in patients with the most severe symptoms. As efficacy has been demonstrated with numerous agents, the improved outcomes are a "class effect" of ACE inhibitors.[30,34]

ACE inhibitor therapy should be started with low doses followed by gradual titration as tolerated to the target or maximally tolerated doses.[34,59] Dose titration is usually accomplished by doubling the dose every 2 weeks. Higher doses further reduce the risk of hospitalization, but not mortality, compared to lower doses.[34] Blood pressure, renal function, and serum potassium should be evaluated at baseline and within 1 to 2 weeks after therapy is started and after each dose increase. Although symptoms may improve within a few days of initiating therapy, it may take weeks to months before the full benefits are apparent. Even if symptoms do not improve, long-term ACE inhibitor therapy should be continued to reduce the risk of mortality and hospitalization.

A number of ACE inhibitors are available; those commonly used in the treatment of patients with HF are summarized in Table 36-7. Although ACE inhibitors vary in their chemical structure (eg, sulfhydryl vs non–sulfhydryl-containing agents) and tissue affinity, all ACE inhibitors studied improve symptoms and mortality in patients with HFrEF.[30,34] However, it seems most prudent to use those agents documented to reduce morbidity and mortality because the dose required for these endpoints has been determined.[34]

Similar to sacubitril/valsartan, the primary adverse effects of ACE inhibitors are secondary to their major pharmacologic action of suppressing angiotensin II and increasing bradykinin. Hence, the most common adverse effects of ACE inhibitors are hypotension, renal dysfunction, and hyperkalemia.

A dry, nonproductive cough is the most common reason for discontinuation of ACE inhibitors, occurring in up to 15% to 20% of patients with a similar frequency with all the agents.[34] The cough usually occurs within the first few months of therapy, resolves within 1 to 2 weeks of drug discontinuation, and reappears with rechallenge. Because cough is a bradykinin-mediated effect, the replacement of ACE inhibitor therapy with sacubitril/valsartan (preferred) or an ARB is reasonable. Angioedema is a potentially life-threatening complication that is also due to bradykinin accumulation and occurs in approximately 1% of patients receiving an ACE inhibitor. It occurs more frequently in patients older than 65 years, Black patients, women, and patients with histories of drug rashes or seasonal allergies.[60] The use of ACE inhibitors is contraindicated in patients with a history of angioedema. Caution should be exercised if ARBs are used as an alternative therapy in patients with ACE inhibitor-induced angioedema, as cross-reactivity is reported.[34] ACE inhibitors are contraindicated in pregnancy due to the increased risk of fetal renal failure, intrauterine growth retardation, and other congenital defects.

Angiotensin II Receptor Blockers

⑤The crucial role of the RAAS in the HF development and progression is well established as are the benefits of inhibiting this system with ACE inhibitors. However, angiotensin II can be formed in a number of tissues, including the heart, through non–ACE-dependent pathways (eg, chymase, cathepsin, and kallikrein).[11] By blocking the angiotensin II receptor subtype, AT1, ARBs attenuate the deleterious effects of angiotensin II on ventricular remodeling, regardless of the site of origin of the hormone. Since ARBs do not inhibit the ACE enzyme, these agents do not affect bradykinin, which is linked to ACE inhibitor cough and angioedema.

While ARBs are a guideline-recommended alternative in patients who are unable to tolerate an ACE inhibitor due to cough or angioedema, sacubitril/valsartan is preferred for patients with cough associated with an ACE inhibitor.[22] Numerous ARBs are available but only three agents, candesartan, valsartan, and losartan, are recommended in the treatment guidelines.[22] The efficacy of these agents is supported by the clinical trial data that document a target dose associated with improved survival and other important outcomes in patients with decreased EF.[34] The specific drugs and doses proven to be effective in clinical trials should be used (Table 36-7). The clinical use of ARBs is similar to that of sacubitril/valsartan and ACE inhibitors. Therapy should be initiated at low doses and then titrated to target doses (Table 36-7). Blood pressure, renal function, and serum potassium should be evaluated within 1 to 2 weeks after initiation of therapy and after increases in the dose, and these monitoring, parameters should be used to guide subsequent dose changes.

The role of ARBs in the treatment of HFpEF is less clear. The CHARM-Preserved trial was the first large prospective study to demonstrate some benefit (reduction in hospitalizations for HF) of an ARB in patients with HFpEF receiving standard background treatment, although no improvement in cardiovascular death was observed.[58] Adverse effects of candesartan in this study were frequent with candesartan-treated patients discontinuing therapy because of hypotension, increased serum creatinine, or hyperkalemia.

Similar to ARNI and ACE inhibitors, the major adverse effects of ARBs are related to the suppression of the RAAS. The incidence of and risk factors for developing hypotension, impaired renal function, and hyperkalemia with the ARBs are similar to those with ARNI and ACE inhibitors.[34] Thus, ARBs are not alternatives in patients who develop these complications from ACE inhibitors. Similar to ACE inhibitors, careful monitoring is required when an ARB is used with an aldosterone antagonist as this combination increases the risk of these adverse effects. Since ARBs do not affect bradykinin, they are not associated with cough and have a lower risk of angioedema than ACE inhibitors.[60] However, because of reports of recurrences of angioedema after ARB use in patients with a history of ACE inhibitor-related angioedema, ARBs should be used with caution in any patient with a history of angioedema as cross-reactivity may occur.[60] Like ARNI and ACE inhibitors, ARBs are contraindicated in pregnancy.

Angiotensin II Receptor Blocker/Neprilysin Inhibitor (ARNI)

⑤ The first and only angiotensin receptor/neprilysin inhibitor approved for the treatment of patients with HFrEF is sacubitril/valsartan. It is a crystalline complex composed of the ARB valsartan and sacubitril, a neprilysin inhibitor prodrug. After ingestion, sacubitril dissociates from the complex and is cleaved into its active form LBQ657, which inhibits the action of neprilysin that degrades natriuretic peptides (NPs), bradykinin, and other endogenous vasodilator and natriuretic peptides.[61] By reducing the neprilysin-mediated breakdown of these compounds, vasodilation, diuresis, and natriuresis are enhanced and renin and aldosterone secretion is inhibited.

The PARADIGM-HF study compared sacubitril/valsartan to enalapril in patients with NYHA Class II-IV HFrEF.[29] There was a statistically significant reduction in the primary outcome of combined death from cardiovascular causes or first hospitalization for HF in patients receiving sacubitril/valsartan compared to enalapril. A similar reduction was seen in each component of the primary endpoint and death from any cause was also significantly reduced. Hypotension occurred more frequently in patients randomized to sacubitril/valsartan compared to enalapril. However, more patients receiving enalapril experienced cough and hyperkalemia greater than 6.0 mEq/L (mmol/L). Angioedema was rare in either treatment group.

In the PARAGON-HF study, patients with HFpEF (LVEF of at least 45% [0.45] and NYHA class II-IV symptoms) were randomized to either sacubitril/valsartan or placebo (Table 36-10).[48] The primary endpoint, a composite of total hospitalizations for HF and death from cardiovascular causes, was not significantly different between the sacubitril/valsartan and placebo groups. A prespecified subgroup in patients with a LVEF in the lower part (45%–57% [0.45-0.57]) of the range suggested benefit. Based upon this subgroup analysis, the indication for sacubitril/valsartan has been expanded to include both those with HFrEF and many, but not all patients, with HFpEF.

In patients with HFrEF, ARNI is preferred over either ACE inhibitors or ARBs to improve survival, slow disease progression, reduce hospitalizations, and improve quality of life.[22] Patients receiving ACE inhibitors or ARBs can be switched to ARNI or ARNI can be used as initial treatment in patients with newly detected HFrEF without previous exposure to ACE inhibitors or ARBs.[22] ACE inhibitors should be discontinued 36 hours prior to initiating ARNI; no waiting period is needed in patients receiving an ARB. The rationale for avoiding overlap is due to an increased risk of angioedema given the neprilysin inhibitor, like an ACE inhibitor, prevents the breakdown of bradykinin. The initial starting dose for most patients being treated for HFrEF is 49/51 mg sacubitril/valsartan twice daily and titrated to the target dose of 97/103 mg sacubitril/valsartan twice daily after 2 to 4 weeks. A reduced dose of 24/26 mg sacubitril/valsartan is available for patients taking a low dose of either an ACE inhibitor or an ARB prior to initiation or those with severe renal dysfunction (eGFR <30 mL/min/1.73 m^2). Blood pressure, serum potassium, and renal function should be closely monitored after the start of therapy and after each titration step. The valsartan component of the combination product is 40% to 60% more bioavailable than conventional valsartan tablets. Thus, the 24-mg sacubitril/26-mg valsartan tablet is equivalent to 40 mg of valsartan.[62]

The primary adverse effects of ARNIs are secondary to their major pharmacologic action of suppressing angiotensin II, increasing bradykinin, and increasing BNP. The most common adverse effects of this agent are hypotension, renal dysfunction, and hyperkalemia. Given similar pharmacologic effects of ACE inhibitors and ARBs, specifically on angiotensin II (ACE inhibitors and ARBs) and bradykinin (primarily ACEIs), a similar side effect profile is generally observed and will be further discussed later in this chapter. ARNIs, ACE inhibitors, and ARBs reduce BP in nearly all patients. Hypotension occurs most frequently soon after therapy is started, after an increase in dose, or in patients who are volume-depleted from diuretics. An often overlooked solution to hypotension is to space the administration times of vasoactive medications (eg, diuretics and β-blockers) throughout the day so that these medications are not all administered at or near the same time.

Functional renal insufficiency causes an increase in serum creatinine and blood urea nitrogen (BUN). As CO and renal blood flow decline, renal perfusion is maintained by the vasoconstrictor effect of angiotensin II on the efferent arteriole. Patients most dependent on this system for maintenance of renal perfusion (and therefore most likely to develop renal insufficiency with an ARNI, ACE inhibitor, or ARB) are those with severe HF, hypotension, hyponatremia, volume depletion, bilateral renal artery stenosis, and concomitant use of NSAIDs.[34,59] Increases in serum creatinine of >0.5 mg/dL (44 μmol/L) if the baseline creatinine is 1 mg/dL (88 μmol/L) if the creatinine is >2 mg/dL (177 μmol/L) should prompt clinicians to dose reduce or discontinue therapy and evaluate potential causes for the abrupt decline in the renal function. Since renal dysfunction with these agents is secondary to alterations in renal hemodynamics, it is almost always reversible on discontinuation of the drug.

Hyperkalemia with ARNI, ACE inhibitors, or ARBs is most likely to occur in patients with renal insufficiency, in elderly patients, and in those taking concomitant potassium supplements, potassium-containing salt substitutes, or potassium-sparing diuretic therapy (including an aldosterone antagonist), especially if they have diabetes.[63] Patiromer or sodium zirconium cyclosilicate can be used to treat or prevent hyperkalemia in these patients.[63]

In contrast to ACE inhibitors, bradykinin side effects of cough and angioedema are rare with both ARNI and ARBs (the latter by virtue of combining sacubitril with the ARB, valsartan, rather than an ACE inhibitor). In fact, ACE inhibitor cough is a common reason to switch to sacubitril/valsartan or an ARB. While extremely rare, angioedema occurred more frequently with sacubitril/valsartan compared to enalapril (0.5% vs 0.2%, respectively).[29] The risk of angioedema is fourfold higher in Black patients.[63] Unlike ACE inhibitor cough, sacubitril/valsartan is contraindicated in patients with a history of angioedema associated with an ACE inhibitor or ARB. Sacubitril/valsartan is also contraindicated in pregnancy and should not be used concurrently with ACE inhibitors or other ARBs. Primarily due to blockade of angiotensin II, ARNIs, ACE inhibitors, and ARBs are contraindicated in pregnancy.

β-Blockers

⑥β-Blockers antagonize the detrimental effects of the SNS in HF and slow disease progression. Favorable effects of β-blockers in HF include antiarrhythmic effects, attenuation or reversal of ventricular remodeling, reduction in myocyte death from catecholamine-induced necrosis or apoptosis, improvement in left ventricular systolic function, reductions in HR and ventricular wall stress thereby reducing myocardial oxygen demand, and inhibition of plasma renin release.[34] There is overwhelming clinical trial evidence that β-blockers reduce morbidity and mortality in patients with HFrEF. As such, the ACC/AHA guidelines on the management of HF recommend that evidence-based β-blockers should be used in all stable patients with HFrEF in the absence of contraindications or a clear history of β-blocker intolerance.[22,34] Patients should receive a β-blocker even if their symptoms are mild or well-controlled with other GDMT. Importantly, it is not essential that doses of other agents (eg, RAAS inhibitors) be optimized before a β-blocker is started because the addition of a β-blocker is likely to be of greater benefit than an increase in the dose of other medications.[22] β-Blockers are also recommended for asymptomatic patients with a reduced left ventricular EF (Stage B) to decrease the risk of progression to HF.[34,64]

Three β-blockers, in particular, reduced morbidity and mortality compared with placebo in randomized, controlled trials: carvedilol, metoprolol succinate (CR/XL), and bisoprolol. Each was studied in a large population with the primary endpoint of mortality, and in each case, the trial was stopped early because of significant survival benefit with the β-blocker. The US Carvedilol Heart Failure Study, the MERIT-HF trial with metoprolol succinate (Toprol-XL®), and the CIBIS II trial with bisoprolol each demonstrated a reduction in mortality; the latter two trials also showed a reduction in sudden death and death due to worsening HF compared with placebo.[65–67] Multiple post hoc subgroup analyses of the MERIT-HF and CIBIS II trials suggest that the benefits of β-blockade occur regardless of HF etiology or disease severity.

In contrast to earlier trials in which the majority of participants had either NYHA class II or class III HFrEF, the COPERNICUS trial examined the efficacy and safety of β-blockers in clinically stable patients with class IV HF who had symptoms at rest or with minimal exertion.[68] Like the other studies, COPERNICUS was stopped early after carvedilol demonstrated a significant reduction in mortality. Carvedilol was well tolerated in this population, with fewer participants receiving carvedilol compared with placebo requiring discontinuation of study medication.

In addition to improving survival, β-blockers improve multiple other endpoints. Clinical trials demonstrate reductions in all-cause hospitalization and hospitalizations for worsening HF with the β-blocker therapy.[67,69,70] Increases in LVEF of 5 to 10 units occur after several weeks to months of therapy. β-Blockers decrease ventricular mass, improve the sphericity of the ventricle, and reduce systolic and diastolic volumes (left ventricular end-systolic volume and LVEDV).[8,34] These effects are often collectively called reverse remodeling, referring to the fact that they return the heart toward a more normal size, shape, and function. β-Blockers are also associated with improvements in NYHA functional class, patient symptom scores or quality-of-life assessments, and exercise performance, as assessed by the 6-minute walk test.

⑥The benefits of β-blockers in HFrEF are not a class effect, therefore, one of the three agents with proven survival benefits (metoprolol succinate, carvedilol, or bisoprolol) should be used.[22] Metoprolol and bisoprolol selectively block the β1-receptor, while carvedilol blocks the β1-, β2-, and α1-receptors and also possesses antioxidant effects. The smallest commercially available tablet of bisoprolol is a scored 5-mg tablet. Since the recommended starting dose of 1.25 mg/day is not readily available, bisoprolol is the least commonly used of the three agents and, in fact, is not approved for use in HFrEF. Thus, therapy is generally limited to either carvedilol or metoprolol succinate, and there is no compelling evidence that one drug is superior to the other. While one trial found a lower mortality rate in patients treated with carvedilol 25 mg twice daily compared to immediate-release metoprolol 50 mg twice daily,[71] concerns regarding the formulation (immediate-release vs sustained-release) and dose (100 vs 200 mg/day) of metoprolol used limit the conclusions that can be drawn from the trial. The efficacy of the immediate-release formulation in reducing mortality in HF has not been proven. Metoprolol succinate provides more consistent plasma concentrations over a 24-hour period and appears to provide more favorable effects on HR variability, autonomic balance, and BP, suggesting that this formulation might be superior to immediate-release metoprolol. Data from HF registries suggest that metoprolol succinate and carvedilol are similarly effective.[72,73]

Pharmacologic differences between β-blockers may aid in the selection of a specific agent. Carvedilol is expected to have greater antihypertensive effects than the other agents because of its α-receptor blocking properties and may be preferred in patients with poorly controlled BP. Conversely, metoprolol or bisoprolol may be preferred in patients with low BP or dizziness and in patients with significant airway disease.

Most participants in β-blocker trials were on ACE inhibitors at baseline since the benefits of these agents were proven prior to β-blocker trials. Whether the approach of starting a β-blocker prior to an ACE inhibitor or ARB is safe and effective is not clear. The risk for decompensation during β-blocker initiation may be greater in the absence of preexisting ACE inhibitor, ARB, or ARNI therapy. Thus, ACE inhibitors, ARBs, or ARNIs are generally started first in most patients, especially if there is evidence of volume overload. Initiating a β-blocker first may be advantageous for patients with evidence of excessive SNS activity (eg, tachycardia) and may also be appropriate for patients whose renal function or potassium concentrations preclude starting an ACE inhibitor, ARB, or ARNI at that time.

Components that are critical for successful β-blocker therapy include appropriate patient selection, drug initiation and titration, and patient education. β-Blockers should be initiated in stable patients who have no or minimal evidence of fluid overload.[34] While β-blockers are typically started in the outpatient setting, initiation of a β-blocker prior to discharge in patients who are hospitalized for decompensated HF increases β-blocker usage compared with outpatient initiation without increasing the risk of serious adverse effects.[74,75] However, β-blockers should not be started in patients who are hospitalized in the intensive care unit or required IV inotropic support. In unstable patients, other HF therapy should be optimized, and then β-blocker therapy reevaluated once stability is achieved.

Initiation of a β-blocker at normal doses in patients with HF may lead to symptomatic worsening or acute decompensation owing to the drug's negative inotropic effect. For this reason, β-blockers are listed as drugs that may exacerbate or worsen HF (see Table 36-4). To minimize the likelihood of acute decompensation, β-blockers should be started in low doses with slow upward dose titration and close monitoring. β-Blocker doses should be doubled no more often than every 2 weeks, as tolerated, until the target or maximally tolerated dose is reached. Uptitration should be avoided if the patient experiences signs of worsening HF, including volume overload and poor perfusion. Fluid overload may be asymptomatic and manifest solely as an increase in body weight. Mild fluid overload may be managed by intensifying the diuretic therapy. Once the patient has been stabilized, dose titration may continue as tolerated until the target or highest tolerated dose is reached. According to current guidelines, target doses are those associated with reductions in mortality in placebo-controlled clinical trials.[34] The starting and target doses achieved in clinical trials are described in Table 36-7. Data with both metoprolol and carvedilol suggest that HR may serve as a guide to the degree of β-blockade, with a greater magnitude of HR reduction associated with greater improvement in survival. Thus, lower β-blocker doses might be considered reasonable if the reduction in HR indicates a good response to β-blocker therapy.[76] Chapter 37, "Acute Decompensated Heart Failure," will discuss optimal management of β-blocker therapy during hospitalization, addressing appropriate scenarios for continuation and withdrawal of β-blocker therapy.

Good communication between the patient and the healthcare provider(s) is particularly important for successful therapy. It is important to educate patients that β-blocker therapy is expected to positively influence disease progression and survival even if there is little to no symptomatic improvement. Patients should understand that dose titration is a long, gradual process. Patients should also be aware that response to therapy may be delayed and that HF symptoms may actually worsen during the initiation period. In the event of worsening symptoms, patients who understand the potential benefits of long-term β-blocker therapy may be more likely to continue treatment.

As previously discussed, the primary utility of beta-blockers in HFpEF is treating comorbid conditions such as HTN, angina, and myocardial infarction. In patients with HFpEF, β-blockers may help to lower and maintain low pulmonary venous pressures by decreasing HR and increasing the duration of diastole. Tachycardia is poorly tolerated in patients with HFpEF for a variety of reasons. However, excessive bradycardia can result in a fall of CO despite an increase in LV filling. Such considerations underscore the need for individualizing therapeutic interventions that affect HR. In general, it is not necessary to start at an extremely low dose and titrate the β-blocker in a slow, progressive fashion in HFpEF as it is in HFrEF. However, because patients tend to be older, have numerous comorbidities, and take many concomitant medications, it is prudent to start with a moderate dose of β-blockers. A meta-analysis examining the effects of β-blocker therapy on clinical outcomes in patients with HFpEF found lower all-cause mortality but no significant reduction for HF hospitalizations in observational studies.[77] In contrast, an individual patient-level meta-analysis found no benefit of β-blocker therapy in patients with HFpEF (EF > 50% [0.5]) in normal sinus rhythm as compared to patients with reduced (EF < 40% [0.4]) or mid-range EF (40%-49% [0.4-0.49]).[78]

Possible adverse effects with β-blocker use in HF include bradycardia or heart block, hypotension, fatigue, impaired glycemic control in diabetic patients, bronchospasm in patients with asthma, and worsening HF. Clinicians should monitor vital signs and carefully assess for signs and symptoms of worsening HF during β-blocker initiation and titration. Hypotension is more common with carvedilol due to its α1-receptor blocking properties. Bradycardia and hypotension generally are asymptomatic and require no intervention; however, β-blocker dose reduction is warranted in symptomatic patients. Fatigue usually resolves after several weeks of therapy, but sometimes requires dose reduction. In diabetic patients, β-blockers may worsen glucose tolerance and can mask the tachycardia and tremor (but not sweating) that accompany hypoglycemia. In addition, nonselective agents such as carvedilol may prolong insulin-induced hypoglycemia and slow recovery from a hypoglycemic episode. Despite this, there is evidence that carvedilol may improve insulin sensitivity and that β-blockers are well tolerated and significantly reduce morbidity and mortality in patients with diabetes and HFrEF. Thus, while β-blockers should be used cautiously in patients with recurrent hypoglycemia, concerns of masking symptoms of hypoglycemia or worsening glycemic control should not preclude β-blocker use in patients with diabetes. Patients with diabetes should be warned of these potential adverse effects and blood glucose should be monitored when initiating, adjusting, and discontinuing β-blocker therapy. Adjustment of hypoglycemic therapy may be necessary with concomitant β-blocker use in diabetics.

Absolute contraindications to β-blocker use include uncontrolled bronchospastic disease, symptomatic bradycardia, advanced heart block without a pacemaker, and acute decompensated HF. However, β-blockers may be tried with caution in patients with asymptomatic bradycardia, COPD, or well-controlled asthma. Particular caution is warranted in patients with marked bradycardia (<55 bpm) or hypotension (systolic BP <80 mm Hg).

Aldosterone Antagonists

⑦ Spironolactone and eplerenone are aldosterone antagonists that work by blocking the mineralocorticoid receptor, the target site for aldosterone, and, thus, they are also referred to as mineralocorticoid receptor antagonists. In the kidney, aldosterone antagonists inhibit sodium reabsorption and potassium excretion. While the diuretic effects with low doses of aldosterone antagonists are minimal, the potassium-sparing effects can have significant consequences as discussed below. In the heart, aldosterone antagonists inhibit cardiac extracellular matrix and collagen deposition, thereby attenuating cardiac fibrosis and ventricular remodeling.[79] Aldosterone antagonists also attenuate the systemic pro-inflammatory state, atherogenesis, and oxidative stress caused by aldosterone. Thus, as with ACE inhibitors and β-blockers, the data on aldosterone antagonists also support the neurohormonal model of HF. In addition, there is evidence that aldosterone antagonists may attenuate aldosterone-induced calcium excretion and reductions in bone mineral density and protect against fractures in HF.[79]

Three randomized, placebo-controlled trials have evaluated low-dose aldosterone antagonism in patients with HFrEF or post-MI and left ventricular dysfunction. In each trial, the aldosterone antagonist was added to the standard therapy, which included an ACE inhibitor and diuretic. While the initial trial was conducted before the benefits of β-blockers were fully appreciated, participants in the latter two trials received β-blockers. All three trials excluded patients with significant renal dysfunction (eg, serum creatinine above 2.5 mg/dL [221 μmol/L]) and elevated serum potassium (eg, above 5 mEq/L [mmol/L]) at baseline.

The RALES trial was the first to examine the efficacy of aldosterone antagonism in HFrEF. Patients with current or recent NYHA class IV HFrEF were randomized to spironolactone 25 mg/day or placebo.[23] The study was stopped prematurely because of a significant reduction in the primary endpoint of total mortality with spironolactone. Spironolactone also significantly reduced hospitalizations for worsening HF and improved symptoms. The EPHESUS trial evaluated eplerenone in patients with left ventricular dysfunction after MI.[24] Treatment with eplerenone titrated to 50 mg/day was associated with significant reductions in mortality and hospitalizations from HF compared to placebo. The EMPHASIS-HF trial demonstrated significant improvements in clinical outcomes with eplerenone, titrated to 50 mg/day (mean dose of 39 mg/day), in patients with NYHA class II HF and an LVEF of 35% [0.35] or less.[25] Eplerenone treatment reduced the primary endpoint of cardiovascular death or HF hospitalization as well as all-cause and cardiovascular mortality and hospitalization for HF.

The TOPCAT trial examined the effect of spironolactone (mean dose 25 mg/day) in patients with HFpEF (EF > 45% [0.45]).[27] There was no difference in the primary outcome composite of death from cardiovascular causes, aborted cardiac arrest, or hospitalization for HF between the spironolactone and placebo groups; however, there was a significant reduction in the risk for hospitalization for HF. There appeared to be a difference in outcomes by region of enrollment. Post hoc analysis showed a greater reduction in the primary outcome with spironolactone among patients from the Americas, but not in those from Eastern Europe.[26] While the prespecified test for an interaction between region and study arm was not significant, differences in baseline characteristics by region and the lower event rate overall in patients from Eastern Europe confound the interpretation of the study results.

For optimal GDMT in patients with HFrEF and NYHA class II-IV symptoms, a low-dose aldosterone antagonist should be used to improve symptoms, reduce the risk of HF hospitalization, and increase survival provided that serum potassium and renal function can be carefully monitored.[22] On the basis of findings from TOPCAT, guidelines recommend adding an aldosterone antagonist to decrease the risk for hospitalization for HF in patients with HFpEF, especially if plasma natriuretic peptide levels are elevated.[30]

Aldosterone antagonist use in clinical trials was associated with significant increases in serum potassium and creatinine. Most trials demonstrated a higher rate of hyperkalemia (serum potassium ≥5.5 mEq/L [mmol/L] or ≥6.0 mEq/L [mmol/L]) with the aldosterone antagonist compared to placebo.[24,25,27] However, hyperkalemia occurs more commonly in clinical practice than in clinical trials.[80] Risk factors for hyperkalemia include impaired renal function, high potassium concentrations, failure to decrease or stop potassium supplements when starting aldosterone antagonists, diabetes, inadequate laboratory monitoring, high potassium intake, and concomitant use of both ACE inhibitors and ARBs or NSAIDs.[81] The ACC/AHA recommended strategies to minimize the risk for hyperkalemia with aldosterone antagonists in HF and are summarized in Table 36-11.[34] Chief among these recommendations is to avoid aldosterone antagonists in patients with renal dysfunction or elevated serum potassium. Serum creatinine may overestimate renal function in the elderly and in patients with decreased muscle mass, in whom creatinine clearance should serve as a guide for the appropriateness of aldosterone antagonist therapy. The risk for hyperkalemia is dose-dependent, and the morbidity and mortality reductions with aldosterone antagonists in clinical trials occurred at low doses (ie, spironolactone 25 mg/day and eplerenone 50 mg/day). Therefore, the doses of aldosterone antagonists should be limited to those associated with beneficial effects in order to decrease the risk for hyperkalemia. Initiation of every other-day dosing is appropriate for patients with marginal renal function or who are otherwise at high risk for hyperkalemia. Notably, both ARNI and SGLT2 inhibitors may reduce the risk of hyperkalemia with aldosterone antagonists.[82] Spironolactone also interacts with androgen and progesterone receptors, which may lead to gynecomastia, impotence, and menstrual irregularities in some patients. Such adverse effects are less frequent with eplerenone owing to its low affinity for the progesterone and androgen receptors.

TABLE 36-11

Recommended Strategies for Reducing the Risk for Hyperkalemia with Aldosterone Antagonists

- Avoid starting aldosterone antagonists in patients with any of the following:
    - Serum creatinine concentration >2.0 mg/dL (177 μmol/L) in women or >2.5 mg/dL (221 μmol/L) in men or a creatinine clearance <30 mL/min/1.73 m^2(0.29 mL/s/m^2)
    - Recent worsening of renal function
    - Serum potassium concentration >5.0 mEq/L (mmol/L)
    - History of severe hyperkalemia
- Start with low doses (12.5 mg/day for spironolactone and 25 mg/day for eplerenone) especially in the elderly and in those with diabetes or a creatinine clearance <50 mL/min/1.73 m^2 (0.48 mL/s/m^2).
- Decrease or discontinue potassium supplements when starting an aldosterone antagonist.
- Avoid concomitant use of NSAIDs or COX-2 inhibitors.
- Avoid concomitant use of high-dose ACE inhibitors or ARBs.
- Avoid triple therapy with an ACE inhibitor, ARB, and aldosterone antagonist.
- Monitor serum potassium concentrations and renal function within 3 days and 1 week after the initiation or dose titration of an aldosterone antagonist or any other medication that could affect potassium homeostasis. Thereafter, potassium concentrations and renal function should be monitored monthly for the first 3 months, and then every 3 months.
- If potassium exceeds 5.5 mEq/L (mmol/L) at any point during therapy, discontinue any potassium supplementation or, in the absence of potassium supplements, reduce or stop aldosterone antagonist therapy.
- Counsel patients to:
    - limit intake of high potassium-containing foods and salt substitutes.
    - avoid the use of over-the-counter NSAIDs.
    - temporarily discontinue aldosterone antagonist therapy if diarrhea develops or diuretic therapy is interrupted.

Data from Reference [34].

Sodium-Glucose Cotransporter Type 2 (SGLT2) Inhibitors

8 Initially developed for diabetes given their glucose-lowering potential by blocking renal tubular glucose reabsorption, SGLT2 inhibitors have also been of benefit in HF. These agents inhibit glucose and sodium reabsorption in the proximal renal tubule which promotes urinary glucose excretion and causes a modest diuresis.[83] Under normoglycemic conditions, the kidneys contribute to blood glucose homeostasis by nearly complete reabsorption of filtered glucose. The majority (>90%) of glucose reabsorption occurs early in the proximal tubule via SGLT2, while the remainder is reabsorbed by SGLT1 in the late proximal tubule. Although the mechanism of benefit from these agents in HF remains uncertain, treatment with SGLT2 inhibitors leads to osmotic diuresis and natriuresis, reduction in arterial pressure and stiffness, and a shift to ketone-based myocardial metabolism. Additional benefit may be related to the reduction of preload and afterload thereby reducing cardiac stress and injury and ultimately leading to reduced myocardial hypertrophy, fibrosis, and remodeling.[32,83]

Cardiovascular outcome trials in patients with type 2 diabetes demonstrated that SGLT2 inhibitors improved both CV and renal outcomes as well as a reduction in hospitalizations for HF. Thus, outcome trials in patients with HF with and without diabetes were designed. In the DAPA-HF and EMPEROR-Reduced trials, patients with HFrEF and NYHA class II-IV symptoms, both dapagliflozin and empagliflozin reduced the risk of worsening HF and cardiovascular death compared to placebo. In addition, both agents demonstrated a significant reduction in each of the individual components of the composite endpoint.[84,85] Importantly, these benefits were observed both in patients with and without diabetes. As a result, both agents are now foundational components of optimal GDMT for patients with HFrEF (with or without diabetes) and are FDA approved for use in this population.[22] In a completed EMPEROR-Preserved trial, empagliflozin (fixed dose of 10 mg daily) also reduced the primary outcome of cardiovascular death or HF hospitalization in patients with HFpEF.[47]

Dosing, monitoring, and related recommendations for SGLT2 inhibitors are detailed in Tables 36-7 and 36-9. The DAPA-HF trial did not enroll patients with an eGFR <30 mL/min/1.73 m^2 and the limit of eGFR for inclusion in the EMPEROR-Reduced trial was 20 mL/min/1.73 m^2. These agents are indicated in patients with renal function above these eGFR thresholds. Renal function (eGFR) may initially decrease with SGLT2 inhibitor initiation but improve over time. Patient counseling is imperative with the use of SGLT2 inhibitors, especially in the HF population. It is unclear if SGLT2 inhibitors will contribute to volume depletion and the potential need for diuretic dose adjustment. And thus, patients should be counseled to weigh daily and contact their healthcare provider should their weight start to decline and to avoid abrupt changes in position as orthostasis may occur in the setting of over diuresis. Patients should be monitored for acute kidney injury and renal function impairment; temporary discontinuation of diuretic may be required in settings of reduced oral intake or fluid losses. Patients should also be advised to monitor for and report mycotic genital infections and urinary tract infections. Urosepsis and pyelonephritis are also potential risks with SGLT2 inhibitors. Necrotizing fasciitis of the perineum, also known as Fournier's gangrene, is a rare but serious and potentially life-threatening adverse effect that may occur in either females or males. Patients presenting with pain or tenderness, erythema, or swelling in the genital or perineal area should also be assessed for fever or malaise. Patients with diabetes may be at increased risk for ketoacidosis and temporary discontinuation before scheduled surgery is recommended to avoid this potential risk. Patients who present with signs and symptoms of metabolic acidosis should be assessed for ketoacidosis, regardless of blood glucose level.

Diuretics

The compensatory mechanisms in HF stimulate excessive sodium and water retention, often leading to pulmonary and systemic congestion.[86,87] Diuretic therapy, in addition to sodium restriction, is recommended in all patients with clinical evidence of fluid retention. Once fluid overload has been resolved, many patients require chronic diuretic therapy to maintain euvolemia. Among the drugs used to manage HF, diuretics are the most rapid in producing symptomatic benefits. However, diuretics do not prolong survival or alter disease progression, and therefore are not considered mandatory therapy. Thus, patients who do not have fluid retention would not require diuretic therapy.

The primary goals of diuretic therapy are to reduce symptoms associated with fluid retention, improve exercise tolerance and quality of life, and reduce hospitalizations from HF. Diuretics accomplish this by decreasing pulmonary and peripheral edema through the reduction of preload. Although preload is a determinant of CO, the Frank-Starling curve (see Fig. 36-4) shows that patients with congestive symptoms have reached the flat portion of the curve. A reduction in preload improves symptoms but has little effect on the patient's SV or CO until the steep portion of the curve is reached. However, diuretic therapy must be used judiciously because over-diuresis can lead to a reduction in CO, renal perfusion, and symptoms of volume depletion.

Diuretic therapy is usually initiated in low doses in the outpatient setting, with dosage adjustments based on symptom assessment and daily body weight. Change in body weight is a sensitive marker of fluid retention or loss, and it is recommended that patients monitor their status by taking daily morning body weights. Patients who gain 1 lb/day (~0.5 kg/day) for several consecutive days or 3 to 5 lb (1.4-2.3 kg) in a week should contact their healthcare provider for instructions (which often will be to increase the diuretic dose temporarily). Such action often will allow patients to prevent a decompensation that requires hospitalization. Patients may be directed to self-adjust their diuretic dose based on changes in HF symptoms and daily body weight. Hypotension or worsening renal function (eg, increases in serum creatinine) may be indicative of volume depletion and necessitates a reduction in the diuretic dose. Assessing volume status is particularly important before ACE inhibitor/ARB/ARNI initiation or dose titration as over-diuresis may predispose patients to hypotension and other adverse effects with these agents.

In patients with HFpEF, diuretic treatment should be initiated at low doses in order to avoid hypotension and fatigue. Hypotension can be a significant problem in the treatment of HFpEF because patients have a steep LV diastolic pressure-volume curve such that a small change in volume causes a large change in filling pressure and CO. Hence, diuretic dosing should be tailored to individual patient needs.

Loop Diuretics

Loop diuretics are usually necessary to restore and maintain euvolemia in HF. They act by inhibiting a Na–K–2Cl transporter in the thick ascending limb of the loop of Henle, where 20% to 25% of filtered sodium normally is reabsorbed. Loop diuretics also induce a prostaglandin-mediated increase in renal blood flow, which contributes to their natriuretic effect. Coadministration of NSAIDs, including cyclooxygenase-2 inhibitors, blocks this prostaglandin-mediated effect and can diminish diuretic efficacy. Excessive dietary sodium intake may also reduce the efficacy of loop diuretics. Unlike thiazides, loop diuretics maintain their effectiveness in the presence of impaired renal function, although higher doses may be necessary to obtain adequate delivery of the drug to the site of action.

There are three loop diuretics available that are routinely used: furosemide, bumetanide, and torsemide.[86,87] They share many similarities in their pharmacodynamics, with their differences being largely pharmacokinetic in nature. Relevant information on the loop diuretics is listed in Tables 36-7 and 36-9. Following oral administration, the peak effect with all the agents occurs in 30 to 90 minutes, with a duration of 4 to 8 hours (longer for torsemide). Following IV administration, the diuretic effect begins within minutes. All three drugs are highly (>95%) bound to plasma proteins, and reach the tubular lumen by active transport via the organic acid transport pathway. The magnitude of the effect is determined by the peak concentration achieved in the nephron, and there is a threshold concentration that must be achieved before any diuresis occurs. Competitors for the organic acid transport pathway (probenecid or organic by-products of uremia) can inhibit the delivery of loop diuretics to their site of action and decrease effectiveness.

The greatest difference between the agents is bioavailability. The bioavailability of bumetanide and torsemide is essentially complete (80%-100%), whereas furosemide bioavailability exhibits marked intra- and inter-patient variability.[86,87] Furosemide bioavailability ranges from 10% to 100%, with an average of 50%. Thus, if bioequivalent IV and oral doses are desired, oral furosemide doses should be approximately double that of the IV dose, whereas IV and oral doses are the same for torsemide and bumetanide. Co-administration of furosemide and bumetanide with food can decrease bioavailability significantly, whereas food has no effect on the bioavailability of torsemide. The intra-abdominal congestion that can occur in HF also may slow the rate (and thus decrease the peak concentration) of furosemide, which can reduce its efficacy. Thus, furosemide is most problematic with respect to the rate and extent of absorption and the factors that influence it, whereas torsemide has the least variable bioavailability.

These differences in bioavailability and variability may have clinical implications. For example, several studies suggest that torsemide is absorbed reliably and may be associated with better outcomes than the more variably absorbed furosemide.[86] Torsemide may modulate neurohormonal levels resulting in attenuation of cardiac remodeling. Torsemide is preferred in patients with persistent fluid retention despite high doses of other loop diuretics. While the costs of torsemide exceed those of furosemide, pharmacoeconomic analyses suggest that the costs of care are similar or less with torsemide.

Heart failure is one of the disease states in which the maximal response to loop diuretics is reduced. This is believed to result from a decrease in the rate of diuretic absorption and/or increased proximal or distal tubule reabsorption of sodium, possibly due to increased activity of the Na–K–2Cl transporter.[86,87] As a consequence, loop diuretics exhibit a ceiling effect in HF, meaning that once the ceiling dose is reached, no additional diuretic response is achieved by increasing the dose. Thus, when this dose is reached, additional diuresis can be achieved by giving the drug more often (twice daily or occasionally three times daily) or by giving combination diuretic therapy. Multiple daily dosing achieves a more sustained diuresis throughout the day. When dosed two or three times daily, the first dose is usually given first thing in the morning and the final dose in the late afternoon/early evening. The appropriate chronic dose of a loop diuretic is that which maintains the patient at a stable dry weight without symptoms of dyspnea. Loop diuretic dose ranges and recommended ceiling doses are listed in Table 36-7.

Diuretics cause a variety of metabolic abnormalities, with severity related to the potency of the diuretic.[86,87] The reader is referred to Chapter 37, "Acute Decompensated Heart Failure" for a detailed discussion on the adverse effects of diuretic therapy. Hypokalemia is the most common metabolic disturbance with thiazide and loop diuretics, which in HF patients may be exacerbated by hyperaldosteronism. Hypokalemia increases the risk for ventricular arrhythmias in HF and is especially worrisome in patients receiving digoxin. It is often accompanied by hypomagnesemia. Since adequate magnesium is necessary for the entry of potassium into the cell, co-supplementation with both magnesium and potassium may be necessary to correct the hypokalemia. Concomitant ARNI, ACE inhibitor/ARB and/or aldosterone antagonist therapy may help minimize diuretic-induced hypokalemia because these drugs tend to increase serum potassium concentration through their inhibitory effect on aldosterone secretion. Nonetheless, the serum potassium concentration should be monitored closely in patients with HF and supplemented appropriately when needed.

Thiazide Diuretics

Thiazide diuretics such as hydrochlorothiazide block sodium reabsorption in the distal convoluted tubule (~5%-8% of filtered sodium). The thiazides, therefore, are relatively weak diuretics and infrequently used alone in HF. However, thiazides or metolazone can be used in combination with loop diuretics to promote a effective diuresis. In addition, thiazide diuretics may be preferred in patients with only mild fluid retention and elevated BP because of their more persistent antihypertensive effects compared with loop diuretics. Given patients with HFpEF often have ongoing uncontrolled HTN, thiazide diuretics may be used to manage this disorder.

Other Treatments for Heart Failure in Select Patients

Nitrates and Hydralazine

⑪ Nitrates and hydralazine were originally combined in the treatment of HFrEF because of their complementary hemodynamic actions. Nitrates, by serving as nitric oxide donors, activate guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) in vascular smooth muscle resulting in venodilation and decreased preload. Hydralazine is a direct-acting arterial vasodilator causing a decrease in SVR and resultant increases in SV and CO (Fig. 36-1). However, the beneficial effects of hydralazine and nitrates extend beyond their hemodynamic actions and are likely related to attenuating the biochemical processes driving HF progression.

Based on the results of initial clinical trials showing ISDN and hydralazine were more effective in African Americans, the African-American Heart Failure Trial (A-HeFT) enrolled self-identified African Americans with NYHA class III or IV HFrEF receiving standard HF therapy and compared outcomes in patients randomized to the fixed-dose combination of hydralazine/Isosorbide dinitrate (BiDil®) or placebo.[88] The trial was terminated early because of a significant reduction in all-cause mortality in patients receiving hydralazine/isosorbide compared with placebo. Based on these results, BiDil® was approved by the FDA to treat HFrEF in African Americans.

Guidelines recommend the addition of hydralazine/ISDN to Black patients with HFrEF with persistent symptoms despite ARNI, β-blocker, aldosterone antagonist, and SGLT2 inhibitor therapy.[22] Hydralazine/ISDN can also be useful in patients unable to tolerate either an ACE inhibitor or ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.

Despite its efficacy, the use of hydralazine/ISDN is limited by the need for three times daily dosing and frequent adverse effects including dizziness, headache, and GI distress. Because of cost, some clinicians use generic hydralazine and ISDN as separate agents, rather than BiDil®. Although the generic and brand name products are not bioequivalent as determined in healthy volunteer studies, it is unknown if these pharmacokinetic differences impact clinical outcomes.

In contrast to the beneficial effects of hydralazine/ISDN in patients with HFrEF, in patients with HFpEF nitrates reduce exercise capacity and do not improve quality of life or plasma NT-proBNP concentrations.[89] Adverse events, including worsening HF and presyncope/syncope, were more frequent with nitrate treatment. These findings suggest that in the absence of another indication for nitrate therapy (eg, angina), nitrates provide no benefits to patients with HFpEF.

Ivabradine

⑪ Ivabradine reduces heart rate and is used in the treatment of HFrEF.[90] Ivabradine selectively inhibits the I_f current responsible for controlling the depolarization rate of the sinus node.[90] By blocking this current, ivabradine slows the spontaneous depolarization of the sinus node resulting in a dose-dependent slowing of the heart rate. Ivabradine does not affect AV conduction, blood pressure, or myocardial contractility.[90]

Elevated resting heart rate (>70-80 BPM) is emerging as an important independent risk factor for adverse outcomes in patients with HFrEF and is associated with increased hospital admissions, disease progression, and mortality.[91] New approaches to address increased heart rate in these patients are needed because, for a variety of reasons, β-blockers are frequently underdosed in clinical practice and the benefits of β-blockers are associated with the degree of heart rate reduction and the dose administered.[91,92] In the SHIFT trial, ivabradine reduced the risk of hospitalization for worsening HF in patients with HFrEF in sinus rhythm.[93] As a result, guidelines recommend the use of ivabradine in patients with HFrEF in sinus rhythm who have a resting heart rate >70 bpm and are receiving maximally tolerated β-blocker doses.[22]

The starting dose of ivabradine in most patients is 5 mg twice daily with meals. After 2 weeks of treatment, the resting heart rate should be evaluated, and if between 50 and 60 bpm, the dose should be continued. If the heart rate is >60 bpm, the dose can be increased to a maximum of 7.5 mg twice daily. If at any point, the heart rate is <50 bpm or if the patient has symptomatic bradycardia, the dose should be reduced by 2.5 mg twice daily. In this case, if the patient is receiving only 2.5 mg twice daily, then ivabradine should be discontinued. Because of the clear benefits of β-blockers on mortality and that many patients treated with β-blockers are under-dosed, clinicians should remember to titrate to the maximum tolerated doses before determining the need for ivabradine. The most common adverse effects associated with ivabradine were bradycardia, atrial fibrillation, and visual disturbances.

Digoxin

⑪ The benefits of digoxin in HF are related to its neurohormonal modulating activity.[94] These benefits occur at low plasma concentrations and little inotropic effect is produced. Digoxin attenuates the excessive SNS activation present in HF patients. Chronic HF is also marked by autonomic dysfunction, most notably suppression of the parasympathetic (vagal) system. Digoxin increases parasympathetic activity in HF patients and leads to a decrease in HR, thus enhancing diastolic filling. The vagal effects also result in slowed conduction and prolongation of AV node refractoriness, thus slowing the ventricular response in patients with atrial fibrillation. This leads to a decrease in HR, which enhances diastolic filling. Because atrial fibrillation is a common complication of HF, the combined neurohormonal and negative chronotropic effects of digoxin may be beneficial for such patients.

The Digitalis Investigation Group (DIG) trial examined the effects of digoxin on survival and hospitalization in patients with HF symptoms, an LVEF of < 45% (0.45), and in sinus rhythm.[95] No significant differences in all-cause mortality were found between patients receiving digoxin and placebo. Digoxin reduced hospitalizations for worsening HF compared with placebo. Among patients with an LVEF greater than 45% (0.45)(HFpEF) who were enrolled in an ancillary DIG trial, there was no apparent benefit of digoxin on hospitalizations or mortality.[96] An analysis of the trial database found that lower serum digoxin concentrations (SDCs) were associated with decreased mortality, whereas higher concentrations were not.[97] Specifically, compared with placebo, SDCs of 0.5 to 0.9 ng/mL (μg/L; 0.6-1.2 nmol/L) were associated with lower mortality, all-cause hospitalizations, and HF hospitalizations. Based on these data, for most patients, the target SDC should be 0.5 to 0.9 ng/mL (μg/L; 0.6-1.2 nmol/L).[34] In most patients with normal renal function, this serum concentration range can be achieved with a daily dose of 0.125 mg. Patients with decreased renal function or low body weight, the elderly, or those receiving interacting drugs (eg, amiodarone) should receive 0.125 mg daily or every other day. Routinely measuring SDCs is not necessary unless digoxin toxicity is suspected or there are other conditions that may significantly affect SDC such as worsening renal function or the initiation of an interacting drug. Digoxin combined with a β-blocker or amiodarone is superior to either agent alone for controlling ventricular response in patients with atrial fibrillation and HF.[34] Therefore, target SDCs are the same regardless of whether the patient is in sinus rhythm or atrial fibrillation. Several equations and nomograms have been proposed to estimate digoxin maintenance doses based on estimated renal function for a particular patient and population pharmacokinetic parameters. These methods are extensively reviewed elsewhere.[98]

The DIG trial was conducted prior to the proven benefits and widespread use of β-blockers in HF. Observational studies have reexamined digoxin in the context of contemporary HF therapy and shown variable results.[99–101] In patients with HFrEF receiving more contemporary GDMT, digoxin withdrawal is associated with an increased risk of hospital readmissions for HF and the combined endpoint of HF readmission and mortality.[102] Based on the totality of data, digoxin is not considered a first-line agent in HF but a trial may be considered in conjunction with GDMT in patients with symptomatic HFrEF to improve symptoms and reduce hospitalizations.[34] Digoxin may also be considered to help control ventricular response rate in patients with HFrEF and supraventricular arrhythmias.

There is no established role for digoxin in HFpEF when patients are in normal sinus rhythm. Digoxin may be of benefit in patients with concomitant HFpEF and atrial fibrillation.[103]

Digoxin pharmacokinetics are well described.[98] There is a long "distribution phase" after administration of oral or IV digoxin, resulting in a lag time before a maximum pharmacologic response is observed. Blood samples for measurement of SDCs should be collected at least 6 hours and preferably 12 hours or more after the last dose. The drug efflux transporter P-glycoprotein (P-gp) plays an important role in the bioavailability, renal and nonrenal clearance, and drug interactions with digoxin. Clinically important pharmacokinetic/pharmacodynamic drug interactions exist with a range of mechanisms including reduced bioavailability through various processes (eg, antacids, cholestyramine, kaolin-pectin, metoclopramide), altered gut bacteria (eg, clarithromycin, tetracycline), reduced clearance through P-glycoprotein inhibition (e.g., cyclosporine, ranolazine, ritonavir) and hypokalemia/hypomagnesemia increasing risk of digoxin toxicity (eg, thiazide or loop diuretics). Select interactions occur through multiple mechanisms such as increased bioavailability and reduced renal and nonrenal clearance through P-glycoprotein inhibition resulting in 50% to 100% or greater increases in serum digoxin concentrations (eg, amiodarone, verapamil, quinidine, ketoconazole, macrolide antibiotics) requiring up to a 50% reduction in dose. One standard GDMT, spironolactone, may alter the clearance of digoxin, and thus close monitoring of serum concentrations is warranted. In addition, spironolactone may interfere with some digoxin assays, thus, increasing apparent digoxin concentrations.

Digoxin can produce a variety of cardiac and noncardiac adverse effects, but it is usually well tolerated by most patients.[94] Noncardiac adverse effects frequently involve the GI (nausea/vomiting) or CNS (halos, photophobia, problems with color perception including red-green or yellow-green vision) systems but also may be nonspecific (eg, fatigue, weakness, confusion). Cardiac manifestations include numerous different arrhythmias caused by the drug's multiple electrophysiologic effects including both various tachy- and bradyarrhythmias ranging from sinus bradycardia to third-degree heart block and premature ventricular contractions to ventricular arrhythmias. Rhythm disturbances are of particular concern because patients with chronic HF are already at increased risk for sudden cardiac death, presumably due to ventricular arrhythmias. Patients at increased risk of toxicity include those with impaired renal function, decreased lean body mass, the elderly, and those taking interacting drugs. Hypokalemia, hypomagnesemia, and hypercalcemia will predispose patients to cardiac manifestations of digoxin toxicity. Thus, concomitant therapy with diuretics may lead to electrolyte abnormalities and increase the likelihood of cardiac arrhythmias. Similarly, hypothyroidism, myocardial ischemia, and acidosis will also increase the risk of cardiac adverse effects. Although digoxin toxicity is commonly associated with plasma concentrations greater than 2 ng/mL (μg/L; 2.6 nmol/L), toxicity may occur at lower concentrations, and clinicians should remember that digoxin toxicity is based on the presence of symptoms rather than a specific plasma concentration.[98] Usual treatment of digoxin toxicity includes drug withdrawal or dose reduction and treatment of cardiac arrhythmias and electrolyte abnormalities. In patients with life-threatening digoxin toxicity, purified digoxin-specific Fab antibody fragments should be administered.

Vericiguat

⑪ One of the detrimental consequences of HF is endothelial dysfunction and reactive oxygen species generation.[104] Vericiguat is a novel pharmacotherapy that modulates endothelial dysfunction.[105] Under normal conditions, the vascular endothelium generates nitric oxide (NO) which stimulates soluble guanylate cyclase (sGC) mediated cyclic guanosine monophosphate (cGMP) production. The endocardial endothelium is also sensitive to NO and relies upon increasing intracellular cGMP to regulate contractility and diastolic function. In HF, this process becomes dysregulated, leading to insufficiency of NO, sGC and cGMP, resulting in impaired diastolic relaxation and microvascular dysfunction. While administration of nitrates, in combination with hydralazine, reduce mortality in HFrEF, this benefit has only been demonstrated in Black patients.[88] Vericiguat is a sGC activator that binds to sGC and enhances the effect of NO to increase cGMP activity.[105]

In the VICTORIA trial, patients with HFrEF (LVEF <45% [0.45]), recent ADHF requiring hospitalization or outpatient intravenous diuretics, and elevated BNP levels were randomized to vericiguat or placebo.[106] Patients receiving vericiguat demonstrated a significant, but modest, reduction in the primary endpoint of cardiovascular death or HF hospitalization. Vericiguat was well tolerated with no differences in symptomatic hypotension or syncope between groups. While renal function and electrolytes were unaffected, there was a concerning and as yet unexplained greater incidence of anemia found in patients receiving vericiguat. The place in therapy for verciguat is unclear given the limited benefit but it may lie in the lack of significant hemodynamic, renal, and electrolyte effects in the setting of a high-risk population that often does not tolerate GDMT. Its use has not been incorporated into current treatment guidelines.[22] Now, vericiguat is not indicated in HFpEF given the lack of benefit and potential lack of safety (hypotension, syncope) demonstrated in the VITALITY-HFpEF Trial.[107]

Calcium Channel Blockers

Calcium channel blockers have a limited role in HFrEF. While dihydropyridine type agents (eg, amlodipine, felodipine) are safe to use in patients with HFrEF, these agents have a neutral effect on morbidity or mortality. Hence, they can be safely used to manage HTN or angina in patients with HFrEF but they should only be considered after other doses of GDMT with blood pressure lowering effects are optimized. In contrast, the nondihydropyridine calcium channel blockers, verapamil and diltiazem, are contraindicated in HFrEF due to their negative inotropic effects. As such, nondihydropyridines are listed as medications that can exacerbate HF in Table 36-4.

Calcium channel blockers can provide symptom-targeted treatment in patients with HFpEF by decreasing HR and increasing exercise tolerance. They can also provide disease-targeted therapy by treating HTN and coronary artery disease. However, the beneficial effect of these agents on exercise tolerance is not always paralleled by improved LV diastolic function or increased relaxation rate. Of the calcium channel blockers, the nondihydropyridines are the most effective because they lower heart rate in addition to lowering BP. Nondihydropyridines are also frequently used to treat the comorbidities of HTN and atrial fibrillation in patients with HFpEF. Sustained-release nifedipine, because of its strong vasodilator properties, tends to cause hypotension, reflex tachycardia, and peripheral edema. These characteristics make it less useful in HFpEF. Amlodipine may be effective because it reduces BP. Initial daily doses are verapamil 120 to 240 mg, diltiazem 90 to 120 mg, and amlodipine 2.5 mg.

Heart block is a contraindication for nondihydropyridines. The most common adverse effects are bradycardia and heart block (for the nondihydropyridines). Peripheral edema and headache also are common. Nondihydropyridines exacerbate the bradycardic effects of β-blockers, and verapamil raises digoxin serum concentrations by 70%. Generic formulations, but not necessarily generic equivalents to the original brand names, are available for some of the calcium channel blockers.

Tafamidis

Tafamidis stabilizes the TTR tetramer by binding to the thyroxine-binding sites and thereby slowing its disassociation into monomers and halting the amyloid deposition process. The Transthyretin Amyloidosis Cardiomyopathy Clinical Trial (ATTR-ACT) included 441 patients with either hereditary (24%) or wild type (76%) ATTR-CM.[17] The trial results showed the superiority of tafamidis meglumine to placebo in reducing all-cause mortality and reducing the rate of hospitalizations due to cardiovascular complications. No differences in the primary outcome were observed between hereditary and wild-type ATTR patients. Approved in the United States in 2019, tafamidis is dosed once daily as either a single 61 mg capsule or four 20 mg capsules (80 mg total) of tafamidis meglumine.

Special Populations

HF is often accompanied by other cardiovascular and non-cardiovascular disorders whose natural history or therapy may affect morbidity, mortality, and treatment approach.[3,33] Optimal management of these concomitant disorders in the context of the patient's HF is an important consideration in the overall care of the patient.

Although HTN has been replaced by ischemic heart disease as the most common cause of HF, up to 90% of patients with HF have a current or a previous history of HTN.[3] HTN directly contributes to the development of both HFrEF and HFpEF as well as indirectly by increasing the risk of coronary artery disease. Effective treatment of HTN markedly reduces the risk of developing HF.[3] Pharmacotherapy of HTN in patients with HFrEF should initially involve GDMT with blood pressure reducing effects (eg, ARNI, β-blockers, aldosterone antagonists). If control of HTN is not achieved after optimizing treatment with these agents, the addition of ISDN/hydralazine or a dihydropyridine calcium channel blocker such as amlodipine may be considered. In patients with HFpEF, both verapamil and diltiazem can be safely used in conjunction with other therapies known to benefit select patients with HFpEF, specifically ARNI or ARBs. In patients with either HFrEF or HFpEF, target levels of BP should be less than 130/80 mm Hg, consistent with current guidelines (see Chapter 30, "Hypertension").[30,36]

Coronary artery disease is the most common cause of HFrEF and a less common cause of HFpEF. Appropriate management of coronary disease and its risk factors is thus an important strategy for the prevention and treatment of HF (see Chapter 32, "Stable Ischemic Heart Disease"). Coronary revascularization should be strongly considered in patients with both HF and angina.[34] Pharmacotherapy of angina in patients with HF should utilize drugs that can effectively treat both disorders. In HFrEF, nitrates and β-blockers are effective antianginals and are the preferred agents for patients with both disorders since they may improve clinical outcomes. In HFrEF, both amlodipine and felodipine are safe to use in this setting while nondihydropyrindines should be avoided. In HFpEF, given nitrates, β-blockers and verapamil have neutral effects on HF outcomes, they can also be safely used. Optimization of treatments for secondary prevention of coronary and atherosclerotic vascular disease should also be considered.[3]

Atrial fibrillation is the most frequently encountered arrhythmia and it is commonly found in both HFrEF and HFpEF, with the prevalence increasing in parallel to the severity of HF and an association with worse long-term prognosis.[34,35] Moreover, HF exacerbations and atrial fibrillation are closely linked causes of hospitalization and it is often difficult to determine which disorder caused the other. Thus, optimal management according to established guidelines is required with careful attention paid to control of ventricular response, symptoms, and anticoagulation for stroke prevention (see Chapter 40, "Arrhythmias").[35,108]

Digoxin is frequently used to slow ventricular response in patients with HF and atrial fibrillation. However, it is more effective at rest than with exercise and it does not affect the progression of HF. In addition, the potential for digoxin to increase mortality in patients with atrial fibrillation is a growing concern.[109] β-Blockers are more effective than digoxin and have the added benefits of improving morbidity and mortality in patients with HFrEF. Combination therapy with digoxin and a β-blocker may be more effective for rate control than either agent used alone. Calcium channel blockers with negative inotropic effects such as verapamil or diltiazem should be avoided in patients with HFrEF but are effective in patients with HFpEF.

There appear to be no differences in outcomes between the rhythm- (restoration and maintenance of sinus rhythm) and rate-control approaches to atrial fibrillation in patients with HF.[35,103] In general, amiodarone and dofetilide are the preferred agents if rhythm control is needed in HFrEF.[103] Class I antiarrhythmics and dronedarone should be avoided in HFrEF. Because of the limited efficacy and potential for serious adverse effects with antiarrhythmic drugs, there is a growing interest in the use of catheter ablation for restoring sinus rhythm in HF.[108,110] Several recent studies have shown an improvement in clinical outcomes after AF ablation in HF patients highlighting the emerging role of the invasive approach in this subset of patients.[110]

Several noncardiovascular diseases warrant special consideration in HF including diabetes, COPD, depression, gout, chronic kidney disease (CKD) and iron deficiency.[33]

Type 2 diabetes is a common comorbid condition in patients with HF with each disorder independently enhancing the risk of the other.[111] Patients with diabetes are at two to fourfold increased risk of developing HF compared to those without diabetes through increased risk of coronary artery disease and multiple other mechanisms.[111] Adequate glycemic control is critical to reducing the risk of HF development and progression.[111] For most patients with diabetes and HF, a more lenient HbA1c goal of 7% to 8% (53-64 mmol/mol) is suggested and should be individualized based on numerous patient characteristics.[111] Metformin is first-line therapy in patients at risk for or with established HF unless contraindications are present.[111] As previously discussed, SGLT2 inhibitors are now standard GDMT for HFrEF.[22] If additional glucose-lowering is needed, a glucagon-like peptide-1 (GLP-1) receptor agonist demonstrating CV benefits (dulaglutide, liraglutide, or semaglutide) should be considered.[111] The dipeptidyl peptidase-4 (DPP-4) inhibitors saxagliptin and alogliptin should be avoided due to the increased risk of HF. If DPP-4 inhibitors are required, sitagliptin or linagliptin could be considered. The thiazolidinediones and sulfonylureas should be avoided. Insulin therapy may be necessary for some patients to achieve glycemic control. Readers are referred to Chapter 94 (“Diabetes Mellitus”) for more in-depth treatment recommendations.

Given COPD (see Chapter 45, “Chronic Obstructive Pulmonary Disease”) co-presents in many patients with HF, concern about the safe use of β-blockers exists.[33] Overall, the benefit of β-blockers in HFrEF outweighs the risk of worsening pulmonary disease with the exception of those with acute bronchospasm. Use of β1-selective agents (eg, bisoprolol, metoprolol succinate) over nonselective agents are preferred and patients should be counseled to monitor for and report worsening pulmonary symptoms.[33] Limited retrospective data suggest preference may be given to the use of ARBs over ACE inhibitors.[33]

While there have been several studies assessing the role of interventions addressing depression in HF patients, it remains unclear if antidepressants have any benefit. Still, antidepressants should still be considered in patients voicing depressive symptoms (see Chapter 88, “Depressive Disorders”). The selective serotonin receptor inhibitors have beensafe in HF, and thus, these agents are preferred over serotonin-norepinephrine receptor inhibitors and TCAs.[33]

Gout (see Chapter 113, “Gout and Hyperuricemia”) is common in HF patients receiving diuretic therapy. Colchicine is safe and effective in patients with HF experiencing an acute gout flare.[33] Close monitoring for gastrointestinal symptoms and myelosuppression is warranted in the setting of renal dysfunction or concomitant use of CYP3A4 or P-glycoprotein inhibitors. If patients do not tolerate or fail colchicine, corticosteroids are an alternative; however, dose and duration should be limited. NSAIDs are contraindicated in patients with HF as is febuxostat. Allopurinol is the preferred urate-lowering therapy.

Present in over 50% of patients with HFrEF, the effect of CKD on serum potassium and creatinine can substantially impact GDMT use, particularly ACE inhibitors, ARBs, ARNI, and aldosterone antagonists.[33] These agents, along with the SGLT2 inhibitors, are also renoprotective and should be used if at all possible in patients with HFrEF and CKD. Potassium binders may be necessary if hyperkalemia develops. Erythrocyte stimulating agents should not be used to correct anemia in patients with HF alone but may be considered in those with concomitant CKD, low hemoglobin concentrations (ie, <10 g/dL [100 g/L; 6.21 mmol/L]), and adequate or repleted iron stores.

Iron deficiency, defined as ferritin <100 ng/mL (mcg/L) or 100 to 299 ng/mL (mcg/L) with a transferrin saturation (TSAT) <20% [0.2]), is present in approximately 50% of patients with chronic HFrEF and 80% of individuals admitted to the hospital for ADHF.[112] Thus, iron studies should be routinely assessed in patients with symptomatic HFrEF, regardless of the presence or absence of anemia. If iron deficiency is present, the total iron deficit should be calculated using the Ganzoni equation and intravenous repletion should occur with iron product selection taking into consideration cost and feasibility (eg, inpatient versus outpatient) to improve symptoms, functional status and reduce HF hospitalizations.[30,33,113]

EVALUATION OF THERAPEUTIC OUTCOMES

Although mortality is an important endpoint, it does not give a complete measure of the overall impact of HF because many patients are repeatedly hospitalized for HF exacerbations and continue to survive, albeit with a significantly reduced quality of life. Thus, some of the more important therapeutic outcomes in HF management, such as prolonged survival or prevention or slowing of the progression of HF, are difficult to quantify in an individual patient. However, after appropriate diagnostic evaluation to determine the etiology of HF, ongoing clinical assessment of patients typically focuses on the evaluation of three general areas: (a) functional capacity, (b) volume status, and (c) laboratory monitoring.

The evaluation of functional capacity should focus on the presence and severity of symptoms the patient experiences during activities of daily living and how their symptoms affect these activities. Questions directed toward the patient's ability to perform specific activities may be more informative than general questions about what symptoms the patient may be experiencing. For example, patients should be asked if they could exercise, climb stairs, get dressed without stopping, check the mail, go shopping, or clean the house. Another important component of the assessment of functional capacity is to ask patients what activities they would like to do but are now unable to perform.

Assessment of volume status is a vital component of the ongoing care of patients with HF. This evaluation provides the clinician with important information about the adequacy of diuretic therapy. Since the cardinal signs and symptoms of HF are caused by excess fluid retention, the efficacy of diuretic treatment is readily evaluated by the disappearance of these signs and symptoms. The physical examination is the primary method for the evaluation of fluid retention, and specific attention should be focused on the patient's body weight, the extent of JVD, the presence of hepatojugular reflux, presence, and the severity of pulmonary congestion, and peripheral edema. Specifically, in a patient with pulmonary congestion, monitoring is indicated for resolution of rales and pulmonary edema and improvement or the resolution of DOE, orthopnea, and PND. For patients with systemic congestion, a decrease or disappearance of peripheral edema, JVD, and hepatojugular reflux is sought. Other therapeutic outcomes include an improvement in exercise tolerance and fatigue, decreased nocturia, and a decrease in HR. Clinicians also will want to monitor BP and ensure that the patient does not develop symptomatic hypotension as a result of drug therapy. Body weight is a sensitive short-term marker of fluid loss or retention, and patients should be counseled to weigh themselves daily, reporting changes of 3 to 5 lb (1.4-2.3 kg) to their healthcare provider so that adjustments can be made in diuretic doses. Patients and healthcare providers should be aware that HF progression may be slowed even though symptoms have not been resolved.

Routine monitoring of serum electrolytes and renal function is required in patients with HF. Assessment of serum potassium and magnesium is especially important because hypokalemia and hypomagnesemia are common adverse effects of diuretic therapy and are associated with an increased risk of arrhythmias and digox in toxicity (hypokalemia). The risk of hyperkalemia is also high as expected with the use of ACE inhibitors, ARBs, ARNI, and aldosterone antagonists and is associated with adverse outcomes.[80,114] A serum potassium ≥4 mEq/L (mmol/L) should be maintained with some evidence suggesting it should be ≥4.5 mEq/L (mmol/L).[115] Assessment of renal function (BUN and serum creatinine) is also an important endpoint for monitoring diuretic and RAAS inhibitor therapy. Common causes of worsening renal function in patients with HF include over-diuresis, adverse effects of RAAS inhibition, and hypoperfusion.

Excellent overviews on approaches to initiating and titrating evidence-based therapies, care coordination, monitoring parameters, therapeutic endpoints, improving adherence, care of common comorbidities that impact treatment, and solutions to frequently encountered problems when evaluating and treating patients with HFrEF are available.[22,59]

ABBREVIATIONS

ACC	American College of Cardiology
ACE	angiotensin-converting enzyme
AHA	American Heart Association
ARB	angiotensin receptor blocker
ARNI	angiotensin-receptor blocker/neprilysin inhibitor

AVP	arginine vasopressin
BNP	B-type natriuretic peptide
BP	blood pressure
BPM	beats per minute
BUN	blood urea nitrogen
cAMP	cyclic adenosine monophosphate
CKD	chronic kidney disease
CO	cardiac output
COX-2	cyclooxygenase-2
CRT	cardiac resynchronization therapy
ESC	European Society of Cardiology
ET	endothelin
GDMT	guideline-directed medical therapy
HF	heart failure
HFpEF	heart failure with preserved ejection fraction
HFrEF	heart failure with reduced ejection fraction
HFSA	Heart Failure Society of America
HR	heart rate
HTN	hypertension
IABP	intra-aortic balloon pump
ICD	implantable cardioverter-defibrillator

SELF-ASSESSMENT QUESTIONS

The next two questions refer to the following case:

A White patient with HFrEF (LVEF 30% [0.3]) has mild fatigue and dyspnea on exertion. Serum electrolytes, creatinine clearance, and other labs are within normal limits and the serum digoxin concentration collected 18 hours after the previous dose is 0.8 ng/mL (μg/L; 1 nmol/L). The blood pressure is 125/75 mm Hg and heart rate is 60 bpm. The patient's cardiovascular drug regimen is unchanged over the previous 3 months and includes:

Lisinopril 10 mg orally daily

Carvedilol 25 mg orally twice daily

Furosemide 40 mg orally twice daily

Digoxin 0.125 mg orally daily

Spironolactone 25 mg orally daily

Atorvastatin 40 mg orally at bedtime

1. Which is the most appropriate change to the patient's therapy?

   A. Initiate amlodipine

   B. Increase the digoxin dose to 0.25 mg/day

   C. Initiate ivabradine

   D. Change lisinopril to sacubitril/valsartan

2. Which should be added to reduce the risk of death and hospitalization in this patient?

   A. Hydralazine/isosorbide dinitrate

   B. Dapagliflozin

   C. Diltiazem

   D. Metformin

3. Sacubitril/valsartan is contraindicated in patients with which of the following?

   A. Hypokalemia

   B. Concomitant therapy with bumetanide

   C. Angioedema with ramipril

   D. Blood pressure >130/80 mm Hg

4. Which medication may exacerbate HFrEF?

   A. Naproxen

   B. Amlodipine

   C. Rosuvastatin

   D. Empagliflozin

5. Which medication can increase wheezing and shortness of breath in a patient with HFrEF and COPD?

   A. Carvedilol

   B. Spironolactone

   C. Bumetanide

   D. Dapagliflozin

6. Which adverse effect of ramipril may be managed by switching to valsartan?

   A. Cough

   B. Hypotension

   C. Hyperkalemia

   D. Fetal toxicity

7. Patients receiving empagliflozin for HFrEF should be counseled on:

   A. The risk of pulmonary toxicity when used with carvedilol

   B. Signs and symptoms of urinary tract infections

   C. The risk of seizures when used with ACE inhibitors

D. Signs and symptoms of volume overload

8. The risk of hyperkalemia is increased when spironolactone is used with?

A. Ivabradine

B. Furosemide

C. Ibuprofen

D. Metolazone

9. Which should be used to monitor loop diuretic therapy in patients with heart failure?

A. Daily weights, serum potassium, serum creatinine

B. Thyroid-stimulating hormone (TSH) and free T4

C. Fasting blood sugar and hemoglobin A1C

D. Fasting lipid profile

10. Which best describes the use of sacubitril/valsartan in patients with heart failure?

A. It is contraindicated in patients with type 2 diabetes

B. ACE inhibitors should be discontinued at least 36 hours before starting sacubitril/valsartan

C. Hypokalemia is a common adverse effect

D. It causes less hypotension than an ACE inhibitor or ARB

11. Hypokalemia is a complication of which medication used to treat heart failure?

A. Carvedilol

B. Eplerenone

C. Losartan

D. Torsemide

12. What is the most appropriate therapy for a patient with HFrEF that develops lisinopril-induced angioedema?

A. Change to ramipril

B. Change to sacubitril/valsartan

C. Change to hydralazine/isosorbide dinitrate

D. Change to amlodipine

13. A patient with Stage C HFrEF is taking sacubitril/valsartan 49/51 mg orally twice daily, dapagliflozin 10 mg orally daily, furosemide 40 mg orally twice daily, digoxin 0.125 mg orally daily, and metoprolol succinate 25 mg orally daily. The patient presents with increasing shortness of breath, fatigue, ankle swelling, and an 8-pound (3.6 kg) weight gain over the past 2 weeks. Labs are significant for serum potassium of 5.2 mEq/L (mmol/L), serum creatinine 1.0 mg/dL (88 μmol/L), and serum digoxin concentration 0.8 ng/mL (mcg/L; 1 nmol/L) collected 18 hours after the last dose. Vital signs are BP 125/75 mm Hg and heart rate 75 BPM. Which is the most appropriate immediate intervention?

A. Increase the furosemide dose to 80 mg twice orally daily

B. Increase the metoprolol dose to 50 mg orally daily

C. Initiate spironolactone 12.5 mg orally daily

D. Increase the digoxin dose to 0.25 mg orally daily

14. A patient with HFrEF (LVEF 30-35% [0.3-0.35]) is in normal sinus rhythm and is receiving sacubitril/valsartan 97/103 mg orally twice daily, dapagliflozin 10 mg orally daily, carvedilol 50 mg orally twice daily, digoxin 0.125 mg orally daily, spironolactone 25 mg orally daily, and furosemide 40 mg orally twice daily. Vital signs are BP 110/75 mm Hg and pulse 85 bpm. All labs are within normal limits. Which would be the most appropriate medication to add to reduce hospitalization?

A. Potassium chloride

B. Ivabradine

C. Diltiazem

D. Vericiguat

15. A patient with HFpEF (LVEF 50-55% [0.5-0.55]) also has diabetes, hypertension, hyperlipidemia, asthma, and atrial fibrillation. Current vital signs are: HR 85 bpm and BP 128/85 mm Hg. Current labs include serum creatinine 1.0 mg/dL (88 μmol/L), serum potassium 4.3 mEq/L (mmol/L), and HgbA1c 6.8% (51 mmol/mol). Current medications include hydrochlorothiazide 25 mg orally daily, lisinopril 10 mg orally daily, atorvastatin 20 mg orally daily, aspirin 81 mg orally daily, metformin 1000 mg orally twice daily, fluticasone 250/50 inhale 1 puff twice daily, and albuterol PRN. Which is the most appropriate medication to add now?

A. Metoprolol succinate

B. Ivabradine

C. Sacubitril/valsartan

D. Amlodipine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** In this patient who remains symptomatic, changing enalapril to sacubitril/valsartan will reduce the risk of mortality and may improve symptoms. See the “Pharmacologic Therapy for Stages B–D HFrEF” section and Fig. 36-7.

2. **B.** In patients with HFrEF with or without diabetes that meet the eGFR criteria, an SGLT2 inhibitor (either dapagliflozin or empagliflozin) is indicated to reduce the risk of major cardiovascular events including mortality and hospitalizations. See the “Pharmacologic Therapy for Stages B–D HFrEF” section and Fig. 36-7.

3. **C.** Entresto® (sacubitril/valsartan) is contraindicated in patients with a history of angioedema with an ACE inhibitor or ARB. See the “Pharmacologic Therapy for Stages B–D HFrEF” section and Table 36-10.

4. **A.** Naproxen is an NSAID and can worsen heart failure by causing fluid retention, worsening renal function, and increasing blood pressure. See Table 36-3.

5. **A.** Carvedilol, a non-selective beta-blockers, can increase the risk of wheezing and shortness of breath in patients with COPD. A selective beta-blocker (eg, metoprolol succinate) should be considered in these patients. The other agents are not associated with pulmonary adverse effects. See the “Pharmacologic Therapy for Stages B–D HFrEF” section and “Special Populations” section.

6. **A.** ACE inhibitors inhibit bradykinin breakdown and can cause cough in up to 15% to 20% of patients. Valsartan, as well as other ARBs, do not affect

bradykinin and are not associated with cough. See the "Pharmacologic Therapy for Stages B–D HFrEF" section.

7. **B.** By increasing urinary glucose excretion, the SGLT2 inhibitors increase the risk of urinary tract infections as well as genital mycotic infections. Patients should be counseled on the signs and symptoms of these infections and the importance of seeking prompt medical attention should they occur. See the "Pharmacologic Therapy for Stages B–D HFrEF" section and Table 36-9.

8. **C.** The risk of hyperkalemia is increased when the aldosterone antagonist spironolactone (or eplerenone) is used with ibuprofen or any other NSAID. See Table 36-11.

9. **A.** Daily weights are useful to monitor the volume status of patients with either HFrEF or HFpEF that are receiving loop diuretics. As these agents can also cause hypokalemia and worsen renal function with excessive volume depletion, serum potassium and creatinine should also be monitored. See the "Pharmacologic Therapy for Stages B–D HFrEF" section and Table 36-9.

10. **B.** ACE inhibitors should be discontinued at least 36 hours before administering sacubitril/valsartan because of the risk of angioedema. See the "Pharmacologic Therapy for Stages B–D HFrEF" section and Table 36-10.

11. **D.** Torsemide, as well as the other loop diuretics furosemide and bumetanide, are associated with an increased risk of hypokalemia. Serum potassium concentrations should be monitored at baseline and 1-2 weeks after initiation or dose change. See the "Pharmacologic Therapy for Stages B–D HFrEF" and Table 36-10.

12. **C.** Hydralazine/isosorbide dinitrate would be most appropriate in this situation. The combination may reduce mortality and is not associated with angioedema. Both ramipril and sacubitril/valsartan are contraindicated in patients with a history of ACE inhibitor-induced angioedema. See the "Pharmacologic Therapy for Stages B–D HFrEF" section and Table 36-10.

13. **A.** This patient is demonstrating signs/symptoms of volume overload (eg, weight gain, increasing SOB, and lower extremity edema) so an increase in the furosemide dose is indicated. Because the patient is experiencing worsening heart failure symptoms, the metoprolol dose should not be increased now. Spironolactone would not be used because of hyperkalemia. The serum digoxin concentration is within the therapeutic range (0.5-0.9 ng/mL [mcg/L; 0.6-1.2 nmol/L]) so the digoxin dose should not be increased. See Table 36-10 and the "Clinical Presentation" box.

14. **B.** This patient is receiving optimal GDMT with maximum dose sacubitril/valsartan, dapagliflozin, carvedilol, and spironolactone. Despite the maximum dose of carvedilol (50 mg twice daily), the patient's resting heart rate remains above 70 BPM. In patients receiving maximally tolerated doses of beta-blockers, the addition of ivabradine targeting a resting heart rate of < 60 BPM, reduces the risk of hospitalization in patients with HFrEF. See the "Other Treatments for Heart Failure in Select Patients" and Tables 36-9 and 36-10.

15. **C.** Sacubitril/valsartan should be added. Recent evidence from the PARAGON trial showed that sacubitril/valsartan reduced the risk of cardiovascular death and hospitalization for heart failure in patients with HF and LVEF > 45% (0.45). See the "Pharmacologic Therapy for HFpEF" section and Table 36-6.

Chapter 37: Acute Decompensated Heart Failure

Brent N. Reed; Stormi E. Gale; Zachary L. Cox

KEY CONCEPTS

KEY CONCEPTS

①Patients presenting to the hospital with acute decompensated heart failure (ADHF) can be categorized into four hemodynamic subsets based on volume status (euvolemic or “dry” vs volume overloaded or “wet”) and cardiac output (adequate cardiac output or “warm” vs hypoperfusion or “cold”). Patients may be warm and dry, warm and wet, cold and dry, or cold and wet.

②While invasive hemodynamic monitoring using a pulmonary artery (PA) catheter does not alter outcomes in a broad population of ADHF patients, it may be considered in those who are refractory to initial therapy, in those whose hemodynamic status is unclear, or in those with clinically significant hypotension (ie, systolic blood pressure <80 mm Hg) or worsening renal function despite standard therapy.

③Key hemodynamic parameters monitored with a PA catheter include pulmonary capillary wedge pressure (PCWP; reflecting fluid status or “preload”), cardiac output or cardiac index (CI; often used to reflect the innate contractility of the heart), and systemic vascular resistance (SVR; reflecting vascular tone or “afterload”). Although a normal PCWP (6–12 mm Hg) is desirable in healthy patients, higher ventricular filling pressures (15–18 mm Hg) are often necessary for patients with heart failure (HF).

④Treatment goals for ADHF include relief of congestive symptoms, restoration of systemic tissue perfusion via improved cardiac output, and minimization of further cardiac damage and other adverse drug reactions.

⑤Optimizing oral chronic HF therapy in the setting of ADHF may assist with improving cardiac output, relieving congestion, and preventing hospital readmission.

⑥Pharmacologic therapies used in the management of ADHF can be broadly classified according to whether they improve volume overload and/or low cardiac output. No therapy studied to date has conclusively been shown to reduce mortality, and some may worsen outcomes.

⑦Intravenous (IV) loop diuretics are considered first-line therapy for the management of ADHF associated with volume overload. Administration as a bolus or continuous infusion appears to be equally effective and safe when selected as initial therapy, although high-dose loop diuretic therapy (ie, 2.5 times the oral regimen prior to admission) is associated with greater volume removal. The addition of a thiazide-type diuretic may be considered in patients with diuretic resistance. If patients continue to be refractory to, or experience worsening of renal function with, diuretic therapy, placement of a PA catheter may helpguide therapies such as IV vasodilators and/or inotropes.

⑧Ultrafiltration may be considered in patients with diuretic resistance or those with worsening renal impairment despite IV vasodilator and/or inotrope therapy.

⑨Intravenous vasodilators may be added to diuretics for rapid resolution of congestive symptoms, especially in patients with acute pulmonary edema or severe hypertension. Such therapy may also be considered in patients who fail to respond to aggressive treatment with diuretics. In the absence of hypotension (systolic blood pressure <90 mm Hg or symptomatic hypotension) or reduced left ventricular filling pressures, IV vasodilators should also be considered prior to IV inotropes in patients with ADHF and evidence of low cardiac output. Frequent blood pressure monitoring is necessary to ensure their safe use.

⑩ Intravenous inotropes are recommended for maintaining systemic perfusion and end-organ function in hypotensive patients with evidence of severe left ventricular dysfunction and low cardiac output. Inotropic therapy may also be considered in patients who do not tolerate or respond to IV vasodilators or in patients with worsening renal function despite standard therapy. Patients receiving IV inotropes should be monitored continuously for arrhythmias.

⑪ Temporary mechanical circulatory support (MCS) is indicated in select patients with severe ADHF or those with advanced HF who are refractory to pharmacologic therapy. The intra-aortic balloon pump (IABP) is the most common type of temporary MCS but provides the least amount of hemodynamic support. Other types of temporary MCS include temporary ventricular assist devices (VADs) and extracorporeal membrane oxygenation (ECMO).

⑫ Cardiac transplantation remains the only definitive therapy for advanced HF. Given the extended wait time for identifying suitable donors, implantation of a durable VAD may be considered for patients who are eligible for cardiac transplantation (ie, "bridge to transplant") or in whom transplantation is not an option (ie, "destination therapy").

BEYOND THE BOOK

BEYOND THE BOOK

Pair up with a classmate and create a series of flashcards, in which you describe and list several characteristics of a patient in one of the four hemodynamic subsets on one side (ie, signs, symptoms, physical examination findings, laboratory values) and the appropriate classification and treatment approach on the other side. Present your partner with the case, and ask them to recommend an initial treatment and monitoring plan. Ensure that at least one of each of the four hemodynamic subsets is represented in your stack of cards, but also try varying the complexity and severity of each case/list. For example, start with a simple case/list of characteristics consistent with fluid overload (ie, subset II or "warm and wet"), and ask your partner to recommend an intravenous diuretic regimen based on the patient's home diuretic dose. Later, progress to patient scenarios/cards representing subset III ("cold and dry") and IV ("cold and wet"). For each case/card, ask your partner to list patient-specific factors that might influence the treatment approach (eg, hypotension when deciding between a vasodilator and inotrope) as well as monitoring parameters for the therapies selected. For an extra challenge, add in some cases/cards where you provide values from a pulmonary artery catheter or include a patient who develops diuretic resistance. Compare and contrast your partner's recommendations with those you wrote on the back of the card.

INTRODUCTION

The clinical course of heart failure (HF) manifests as periods of relative stability with increasingly frequent episodes of decompensation as the disease progresses.[1] Several terms have been used to characterize worsening HF requiring hospitalization. Patients with persistent symptoms requiring specialized interventions despite guideline-directed medical therapy (GDMT) are classified as having advanced HF or Stage D, according to the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) system.[2] Due to the presence of HF symptoms with minimal activity or at rest, these patients are also typically classified as New York Heart Association (NYHA) class III or IV, respectively. The terms *acute decompensated heart failure* (ADHF) and *exacerbation of heart failure* refer to those patients with new or worsening signs or symptoms of HF (often as a result of volume overload and/or low cardiac output [CO]) requiring medical intervention such as an emergency department visit or hospitalization. The term *acute heart failure* may be misleading as it more often refers to patients with a sudden onset of HF signs or symptoms following previously normal cardiac function (eg, following myocardial infarction [MI]). This chapter focuses on the management of patients with ADHF, which may include those with heart failure with reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF).

Despite the considerable morbidity and mortality associated with ADHF, few randomized controlled trials have been conducted in this patient population. For those studies that have been published, the heterogeneity of patients enrolled often limits clinical application. Nonetheless, clinical practice guidelines for HF issued by ACCF/AHA include sections specifically focused on the management of advanced HF and ADHF; these and other consensus-based recommendations will be referenced where relevant throughout this chapter.[2,3]

EPIDEMIOLOGY

An estimated 6 million American adults have HF, and projections indicate that prevalence is likely to increase nearly 50% by 2030.[4] The growing number of patients living with HF has led to substantial increases in hospitalization rates for ADHF. Recent data indicate that over 1 million patients are hospitalized for HF annually, contributing to significant increases in morbidity and mortality and adding substantial burden to the healthcare system.[4,5] Hospitalization for HF has been independently associated with increases in subsequent hospitalization as well as decreased survival, which may explain why the mortality rate at five years remains high (42.3%).[4,6] The cost of HF is projected to approach $70 billion by 2030, an increase thought to be driven primarily by the costs of acute care.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

The underlying etiology of ADHF varies and is often multifactorial. De novo HF may occur due to left ventricular dysfunction following a large MI or sudden elevation in blood pressure; such cases represent approximately 25% of admissions.[6] However, most hospitalizations for ADHF (70%) comprise patients experiencing an acute worsening of chronic HF;[7] readers are referred to Chapter 36, “Chronic Heart Failure,” for a more detailed discussion of the etiology and pathophysiology of chronic HF including precipitating factors. Patients can become refractory to oral therapies and decompensate after even a relatively mild insult (eg, dietary indiscretion, nonsteroidal anti-inflammatory drug use), medication nonadherence, or concurrent noncardiac illness (eg, infection). New or worsening cardiac processes, such as MI, atrial or ventricular arrhythmias, hypertensive crises, myocarditis, or acute valvular insufficiency, may also produce ADHF in an otherwise stable patient. Exacerbations of chronic HFrEF and HFpEF occur in approximately equal numbers.[2] A minority of patients (5%) present with gradual, progressive worsening of CO and refractoriness to therapy due to advanced left ventricular systolic dysfunction.[7]

Several studies have provided a better understanding of the prognostic factors associated with ADHF. Blood urea nitrogen (BUN) is the best individual predictor of in-hospital mortality, followed by low systolic blood pressure and elevated serum creatinine.[8] Hyponatremia, elevations in troponin I, ischemic etiology, and poor functional capacity are also negative prognostic factors.[6,9] Use of GDMT at discharge and coronary angiography or implantable cardioverter-defibrillator placement during hospitalization are associated with improved prognosis, suggesting that optimal management during hospitalization can yield beneficial effects on subsequent prognosis.[9]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Acute Decompensated Heart Failure

General

- Patients with ADHF typically present in one of four hemodynamic subsets (Fig. 37-1) based on the presence of volume overload (ie, congestion) and/or low cardiac output (ie, tissue hypoperfusion).
- Hemodynamic status can be ascertained in most patients based on their history and physical examination; some may require invasive hemodynamic monitoring.

Symptoms

- Volume overload: dyspnea, orthopnea, paroxysmal nocturnal dyspnea, ascites, gastrointestinal symptoms (poor appetite, nausea, early satiety), peripheral edema, weight gain.
- Low output: altered mental status, fatigue, gastrointestinal symptoms (similar to volume overload), decreased urine output.

Signs

- Volume overload: pulmonary crackles (or rales), elevated jugular venous pressure, abdominojugular reflux, S3 gallop, peripheral edema.
- Low output: tachycardia, hypotension (more commonly) or hypertension, narrow pulse pressure, cool extremities, pallor, cachexia.

Laboratory Values

- Volume overload: B-type natriuretic peptide <100 pg/mL (ng/L; 29 pmol/L) and N-terminal B-type natriuretic peptide <300 pg/mL (ng/L; 35 pmol/L) are negatively predictive for congestive ADHF; serum sodium concentration <130 mEq/L (mmol/L); elevated alkaline phosphatase; elevated gamma-glutamyl transferase.
- Low cardiac output: evidence of end-organ injury due to impaired perfusion, such as elevated liver transaminases and serum creatinine; mixed venous oxygen concentration <60% (0.60); elevated serum lactate.

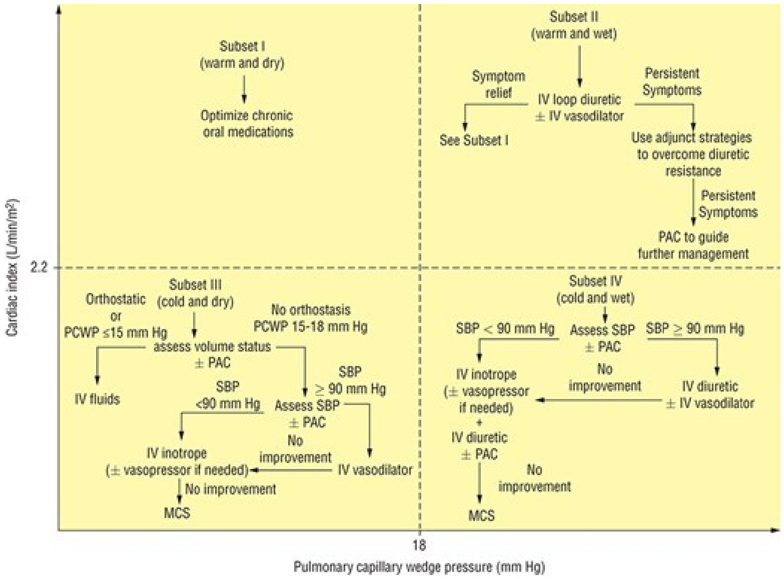
Hemodynamic Monitoring

- Volume overload: pulmonary capillary wedge pressure >18 mm Hg; other volumetric pressures (eg, right atrial pressure, pulmonary artery diastolic pressure) are also commonly elevated.
- Low cardiac output: cardiac index <2.2 L/min/m^2 (0.037 L/s/m^2), with or without systemic vascular resistance >1400 dyne·sec·cm^{-5} (18 Wood units; 140 MPa·s/m^3).

① A careful history and physical examination are key components of an ADHF diagnosis. The history should focus on potential etiologies of ADHF; the presence of precipitating factors; the onset, duration, and severity of symptoms; and a careful medication history. Hemodynamic status should also be ascertained to guide initial therapy. Patients presenting with ADHF may be categorized into one of four hemodynamic subsets based on volume status (euvolemic or "dry" vs volume overloaded or "wet") and CO (adequate CO or "warm" vs hypoperfusion or "cold"). The corresponding subsets are warm and dry (subset I), warm and wet (subset II), cold and dry (subset III), or cold and wet (subset IV; Fig. 37-1). The term *cardiogenic shock* may also be used to describe patients in subsets III and IV who present with low blood pressure and evidence of tissue hypoperfusion. In addition to guiding therapeutic decision-making, these four hemodynamic profiles are also predictive of clinical outcomes. Compared to dry-warm patients, patients in the wet-warm and wet-cold subsets have a 2-fold and 2.5-fold greater risk of death at 1 year, respectively.[7]

FIGURE 37-1

General management algorithm for ADHF based on clinical presentation. Patients may be categorized into a hemodynamic subset based on signs and symptoms or invasive hemodynamic monitoring. Adjunct strategies for overcoming diuretic resistance include increasing the dose of loop diuretic; switching to a continuous infusion; adding a diuretic with an alternative mechanism of action, an IV vasodilator, or an IV inotrope; and in select patients, adding MCS (IV, intravenous; MCS, mechanical circulatory support; PAC, pulmonary artery catheter; PCWP, pulmonary capillary wedge pressure; SBP, systolic blood pressure).



Subset I
(warm and dry)
Optimize chronic oral medications
Subset II
(warm and wet)
Symptom relief
IV loop diuretic ± IV vasodilator
Persistent Symptoms
See Subset I
Use adjunct strategies to overcome diuretic resistance
Persistent Symptoms
PAC to guide further management
Cardiac index (L/min/m²)
2.2
Subset III
(cold and dry)
Orthostatic or PCWP ≤15 mm Hg
No orthostasis PCWP 15-18 mm Hg
assess volume status ± PAC
IV fluids
SBP <90 mm Hg
SBP ≥ 90 mm Hg
Assess SBP ± PAC
IV inotrope (± vasopressor if needed)
No improvement
IV vasodilator
No improvement
MCS
Subset IV
(cold and wet)
SBP < 90 mm Hg
Assess SBP ± PAC
SBP ≥ 90 mm Hg
IV inotrope (± vasopressor if needed) + IV diuretic ± PAC
No improvement
IV diuretic ± IV vasodilator
No improvement
MCS

Although hemodynamic status can be determined in most patients based on signs and symptoms, a small subset of patients may require invasive hemodynamic monitoring to guide therapy. In this latter population, measurement of the pulmonary capillary wedge pressure (PCWP) and cardiac index (CI) may be used to categorize patients by volume status and CO, respectively. A PCWP greater than 18 mm Hg often reflects volume overload and is generally used to distinguish "wet" from "dry" subsets, whereas a CI less than 2.2 L/min/m^2 (0.037 L/s/m^2) is often used to distinguish "cold" from "warm" subsets; use of these invasive hemodynamic parameters will be discussed in further detail later in this chapter.

Hospitalization for ADHF should be considered based on the clinical findings listed in Table 37-1. Most patients do not require admission to an intensive care unit and may be admitted to a monitored unit or general medical floor. If a patient experiences hemodynamic instability necessitating frequent monitoring of vital signs, invasive hemodynamic monitoring, or rapid titration of IV medications (with concurrent monitoring), admission to an intensive care unit may be required to ensure optimal outcomes.

TABLE 37-1

Indications for Hospitalization in Patients Presenting with ADHF

Presenting Features	Clinical Findings
Evidence of fluid overload	Weight gain >10 kg (consider if >5 kg) Symptoms of congestion (eg, dyspnea on exertion or at rest, orthopnea, PND, and early satiety[a]) Signs of congestion (eg, tachypnea with oxygen saturation <90% (0.90), JVD, crackles, hepatomegaly, and lower extremity edema)
Evidence of low cardiac output	Extreme fatigue Hypotension, narrow pulse pressure Cool extremities
Evidence of organ hypoperfusion	Worsening renal or hepatic function Altered mental status
Concomitant cardiovascular diseases that could compromise hemodynamic status	Uncontrolled hypertension Myocardial ischemia or infarction Valvular disease Arrhythmia (eg, atrial fibrillation with rapid ventricular response, ventricular tachycardia, and repeated ICD shocks)
Other conditions that could compromise hemodynamic status	Severe electrolyte deficiency (potassium and magnesium) Acute exacerbation of pulmonary disease (eg, asthma, COPD, or pulmonary embolus) Infection such as pneumonia or urosepsis Symptomatic hypothyroidism or hyperthyroidism Use of medications with negative inotropic effects (eg, nondihydropyridine calcium antagonists)

COPD, chronic obstructive pulmonary disease; ICD, implantable cardioverter defibrillator; JVD, jugular venous distension; PND, paroxysmal nocturnal dyspnea.

[a] Early satiety may also be a symptom of low cardiac output.

Signs and Symptoms

Important elements of the physical examination include assessment of vital signs and weight, cardiac auscultation for heart sounds and murmurs, pulmonary auscultation for crackles, presence and severity of peripheral edema, and evidence of end-organ dysfunction. The most common presentation of ADHF is severe volume overload. Symptoms consistent with pulmonary congestion include orthopnea and dyspnea with minimal exertion, and those associated with systemic congestion include gastrointestinal (GI) discomfort, ascites, and peripheral edema. Orthopnea is the symptom that best correlates with elevated pulmonary pressure, whereas jugular venous pressure is the most reliable sign of volume status, warranting evaluation at admission as well as throughout hospitalization as an indicator of diuretic efficacy.[7] An S3 gallop, suggestive of increased volume in the left ventricle, has high diagnostic specificity for ADHF.[7] Other physical findings, such as pulmonary crackles and lower extremity edema, have low specificity and sensitivity for the diagnosis of ADHF.

Signs and symptoms of low CO are often nonspecific and may include generalized fatigue, cool extremities, and pallor. Manifestations of impaired end-organ perfusion may also be present, such as altered mental status (decreased perfusion to the central nervous system) or decreased urine output (decreased renal perfusion). Hypotension and narrow pulse pressure may also suggest low CO. Gastrointestinal symptoms such as poor appetite, nausea, and early satiety may be a sign of poor perfusion to the GI tract, abdominal congestion, or both. Many patients will present with signs and symptoms of both wet and cold subsets; in these patients, symptoms of low CO may not be obvious until the congestion has been optimally treated.

Laboratory Findings

Plasma B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) concentrations are positively correlated with the degree of left ventricular dysfunction and HF, and are now frequently used to assist in the differential diagnosis of dyspnea (HF vs pulmonary disorders). A low BNP concentration, often defined as less than 100 pg/mL (ng/L; 29 pmol/L), is highly predictive for excluding HF as an underlying etiology for dyspnea.[7] An NT-proBNP concentration of less than 300 pg/mL (ng/L; 35 pmol/L) is similarly predictive for excluding HF. In addition, an elevated BNP concentration prior to discharge is associated with an increased risk of poor long-term outcomes. However, some limitations exist. For example, any disease process that increases right heart pressures will elevate BNP, such as pulmonary emboli, chronic obstructive lung disease, and pulmonary arterial hypertension. In addition, BNP concentrations may be mildly increased with advanced age, female gender, renal dysfunction, and use of sacubitril/valsartan, and may be lower in the setting of obesity. Although the role of BNP in HF remains an area of ongoing research, guidelines recommend obtaining a BNP or NT-proBNP in order to assist with clinical decision-making when the diagnosis of ADHF is uncertain and for determining the prognosis or severity of disease.[2]

A number of other laboratory tests should also be obtained to identify precipitating factors for ADHF (eg, thyroid function tests, complete blood count to assess for infection). In particular, cardiac enzymes (eg, troponin) should be obtained to exclude the presence of myocardial ischemia. Routine serum chemistries (eg, serum creatinine, liver function tests) should also be obtained to assess end-organ perfusion. Ferritin, serum iron, and transferrin iron-binding capacity should be obtained to screen for iron deficiency, even in patients without anemia. Profound volume overload may also contribute to aberrations in serum markers of end-organ function due to venous congestion. Other helpful laboratory tests include markers of peripheral tissue perfusion, such as venous oxygenation saturation and serum lactate concentrations.

Invasive Hemodynamic Monitoring

② Invasive hemodynamic monitoring is usually performed with a flow-directed pulmonary artery (PA) catheter (also known as Swan-Ganz catheter) placed percutaneously into a central vein and advanced through the right side of the heart and into the PA. This process may also be referred to as right heart catheterization (in contrast to left heart catheterization, which is often used to visualize the coronary arteries). Because routine use of a PA catheter in patients with ADHF does not improve survival, invasive hemodynamic monitoring should be reserved for select patients with ADHF.[10] For example, it often provides important information in patients whose clinical status is unclear or complicated (eg, cardiogenic shock), or as a guide for titrating rapidly acting medications (eg, IV vasodilators).[3] As a consequence, invasive hemodynamic monitoring should be considered in patients who are refractory to initial therapy, whose volume status is unclear, or who have clinically significant hypotension (eg, systolic blood pressure <80 mm Hg) or worsening renal function (WRF) despite appropriate initial therapy.[11] Hemodynamic assessment is also required in patients being evaluated for mechanical circulatory support (MCS) or cardiac transplantation. Finally, documentation of an adequate hemodynamic response to IV inotropic therapy is often necessary in order to obtain approval for reimbursement for chronic outpatient inotropic therapy.[2]

③ Several important hemodynamic parameters can be obtained from a PA catheter. Inflation of a balloon proximal to the end port allows the catheter to be "wedged" inside a pulmonary capillary, yielding the PCWP. In the absence of an intracardiac shunt, mitral valve disease, or severe pulmonary disease, the PCWP may be used to estimate left ventricular end-diastolic pressure, or "preload." Preload refers to the stretch incurred by cardiac myocytes in response to increased volumetric pressure. Thus, PCWP can be a useful marker of volume status; elevated PCWP is often indicative of volume overload, whereas reduced PCWP indicates dehydration or inadequate ventricular filling pressure. The relationship between preload (or PCWP) and CO is described by the Frank-Starling mechanism, which is depicted in Fig. 37-2. Due to the much flatter curve observed in patients with HF, increases in preload do not confer the same improvements in CO observed in patients with normal cardiac function. Consequently, higher pressures (ie, 15-18 mm Hg, compared to a normal range of 6-12 mm Hg) are often required in patients with HF in order to optimize CO. Excess preload (PCWP >18 mm Hg) manifests as signs and symptoms of congestion. Fortunately, PCWP can be lowered to 15 to 18 mm Hg with relatively little decrease in CO due to the flatter shape of the Frank–Starling curve in HF. Extreme elevations in PCWP (representing profound volume overload) are also thought to worsen cardiac function, although a precise mechanism for this phenomenon is unknown. Of the parameters that can be obtained via PA catheterization, an elevated PCWP is most consistently associated with a worse prognosis.[12,13]

FIGURE 37-2

Hemodynamic alterations in HF. (A) An illustration of the relationship between cardiac output (displayed as cardiac index, which is cardiac output normalized for body surface area) and preload (displayed as pulmonary capillary wedge pressure) according to the severity of left ventricular function. (B) An illustration of the corresponding relationship between cardiac output and afterload (displayed as systemic vascular resistance). (LV, left ventricular)

A PA catheter may also be used to determine CO or the volume of blood being pumped by the heart (particularly by the left ventricle) over a unit of time. CO is often normalized for body surface area to yield CI, which allows measurements to be made without considering the body size. Using parameters derived from the PA catheter, CO is calculated based on one of two methods. The thermodilution method for determining CO is performed by releasing cooled fluid from a proximal port on the PA catheter and measuring the resulting change in temperature at a downstream thermistor over a period of time. In the Fick method, blood flow is calculated using the difference between arterial and venous oxygen concentration, the oxygen-carrying capacity of hemoglobin, and a population constant for oxygen consumption over time. The preferred method for determining CO varies by clinician, although the presence of certain comorbid conditions (eg, valvular abnormalities and pulmonary disease) may make one method more or less accurate in an individual patient. However, because the determination of CO by the Fick method depends on a set of assumptions (eg, rate of oxygen consumption according to gender and body size), the thermodilution method is generally thought to be a more reliable predictor of outcomes in critically ill patients.[14]

The systemic vascular resistance (SVR) can also be calculated using parameters measured by the PA catheter, including CO, mean arterial pressure (MAP), and central venous pressure (CVP). Also referred to as total peripheral resistance or arterial impedance, SVR reflects "afterload," or the total sum of forces impeding the ejection of blood from the left ventricle. Vasoconstriction (ie, decreased diameter of arterial vessel lumen) increases vascular resistance, whereas vasodilation decreases it. Although SVR is inversely related to CO, patients with normal left ventricular function can often withstand relatively high elevations in SVR, as shown in Fig. 37-2. However, in patients with HF, even a moderately elevated SVR can compromise left ventricular performance. Elevated SVR is common in untreated HF and generally responsive to oral or IV vasodilators. Conversely, a reduction in resistance is consistent with vasodilatory shock (eg, sepsis) and is routinely managed with IV vasopressor therapy (see Chapter e42, "Shock Syndromes").

When the heart rate is held constant, CO reflects stroke volume, or the volume of blood being pumped by the heart (particularly by the left ventricle) with each beat. Although stroke volume is in part determined by cardiac contractility, it is also influenced by preload and afterload, and alterations in CO (or CI) should therefore be interpreted in the context of PCWP and SVR. For example, a low CI (<2.2 L/min/m^2[0.037 L/s/m^2]) in the setting of a low PCWP (<6 mm Hg) may represent decreased preload due to hypovolemia rather than impaired contractility (Fig. 37-2). Similarly, a low CI in the setting of high SVR (>1400 dyne·sec·cm^{-5} [18 Wood units; 140 MPa·s/m^3]) may represent impaired left ventricular performance due to excess afterload (Fig. 37-2). In both of these cases, CI could be increased directly (via inotropic therapy, for example), but a more optimal strategy would be to first address the aberrations in PCWP or SVR contributing to low CI.

A PA catheter can also be used to measure pulmonary vascular resistance (PVR), which represents the impedance of blood flow from the right ventricle to the pulmonary circulation. Pulmonary hypertension and pulmonary edema are two common causes of elevated PVR. Just as SVR is calculated using MAP, PVR is calculated using the mean PA pressure, which incorporates the PA systolic and diastolic pressures. The PA diastolic pressure may also be useful if the PA catheter fails to wedge (making it impossible to obtain PCWP). If the PCWP and PA diastolic pressure have been correlated prior to the failure to wedge, then the PA diastolic pressure may be followed as a surrogate marker of volume status. Normal values for these hemodynamic parameters are listed in Table 37-2.

TABLE 37-2

Normal Hemodynamic Values

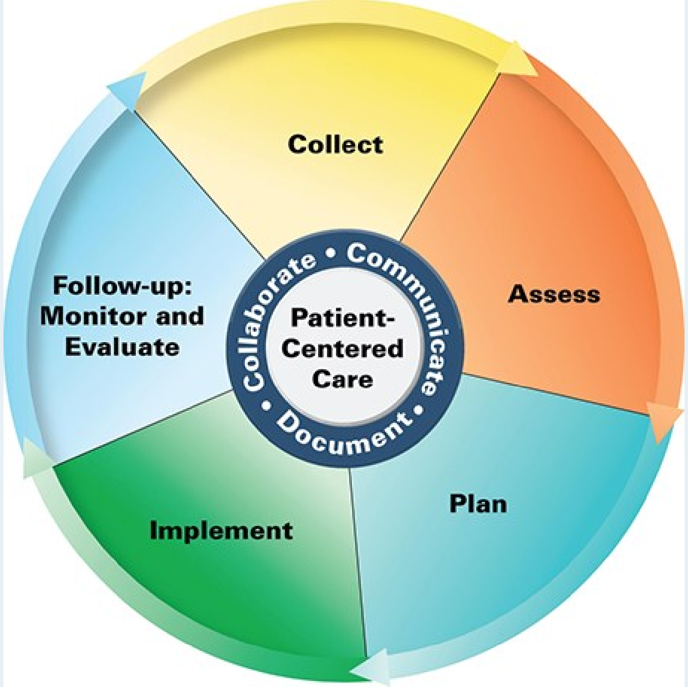
Central Venous (Right Atrial) Pressure, mean, CVP	<5 mm Hg
Right Ventricular Pressure (Systolic/Diastolic)	25/0 mm Hg
Pulmonary Artery Pressure (Systolic/Diastolic), PAS/PAD	25/10 mm Hg
Pulmonary Arterial Pressure, mean, PAP	<18 mm Hg
Pulmonary Capillary Wedge Pressure, PCWP	<12 mm Hg[a]
Systemic Arterial Pressure (Systolic/Diastolic), SBP/DBP	120/80 mm Hg
Mean Arterial Pressure, MAP = (DBP+[1/3 (SBP-DBP])	70-110 mm Hg
Cardiac Output, CO	4-6 L/min
Cardiac Index, CI = CO/BSA	2.8-4.2 L/min/m^2 (0.047-0.070 L/s/m^2)
Systemic Vascular Resistance, SVR = ([MAP–CVP]*80)/(CO)	800-1,400 dyne·sec·cm^{-5} (10-18 Wood units; 80 - 140 MPa·s/m^3)
Pulmonary Vascular Resistance, PVR = ([PAP–CVP]*80)/(CO)	100-200 dyne·sec·cm^{-5} (1.25-2.5 Wood units; 10 - 20 MPa·s/m^3)
Arterial Oxygen Saturation	90%-94% (0.90-0.94)
Mixed Venous Oxygen Saturation	60%-80% (0.60-0.80)

BSA, body surface area.

[a] A higher than normal pulmonary capillary wedge pressure (ie, 15-18 mm Hg) is often accepted in patients with HF. See text for details.

PATIENT CARE PROCESS

Patient Care Process for Acute Decompensated Heart Failure (ADHF)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect (see Tables 37-1 and 37-6)

- Patient characteristics (eg, age, sex, genetic ancestry, pregnancy status)
- Patient medical history (personal and family)
- Social history (eg, tobacco, ethanol, illicit drug use) and dietary habits, including fluid intake and sodium-containing foods
- Current medications, including over-the-counter (OTC) medications (especially nonsteroidal anti-inflammatory drug [NSAID] and decongestant use), herbal products, and dietary supplements
- Subjective data
    - Signs/symptoms of fluid overload (eg, weight changes, dyspnea on exertion or at rest, orthopnea, paroxysmal nocturnal dyspnea, abdominal fullness, lower extremity edema, early satiety)
    - Signs/symptoms of low cardiac output (eg, fatigue, dyspnea on exertion, early satiety)
    - Signs/symptoms associated with precipitating factors (eg, chest pain, palpitations, presyncope, and syncope)
    - Distance patient is able to walk on a flat surface and incline, and the ability to climb one to two flights of stairs
    - Ability to complete activities of daily living
    - Additional diuretic doses taken
    - Adherence to medications and dietary restrictions
    - Home recording of weight and vital signs if available
- Objective data
    - Weight on admission and daily throughout hospital stay (standing weight preferred if not bedridden)

  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), and arterial oxygen saturation every one to six hours depending on the severity of illness
  - Continuous telemetry monitoring, especially if administering intravenous inotropes or if concerned for arrhythmias
  - Pertinent laboratory values, especially sodium, potassium, serum creatinine, blood urea nitrogen (BUN), liver function tests, B-type natriuretic peptide
  - Additional laboratories depending on the severity of illness and other comorbid conditions
  - Various diagnostic tests depending on presumed etiology of acute decompensation, the severity of illness, and drug therapy selection
    - Echocardiogram if symptoms suggest disease progression
    - Electrocardiogram if symptoms suggest new onset or worsening arrhythmia
    - Left heart catheterization if symptoms suggest new ischemia or worsening myocardial ischemia
    - Right heart catheterization (ie, placement of a pulmonary artery catheter) to guide the use of intravenous vasodilators and inotropes (in select patients) or to evaluate for advanced therapies

Assess (see Table 37-1; Figs. 37-1 and 37-2)

- Potential etiologies of decompensation (eg, dietary indiscretion, medication nonadherence)
- Volume status (eg, increase in weight, signs/symptoms of fluid overload)
- Perfusion status (eg, complaints of fatigue, objective data consistent with low cardiac output)
- Ability/willingness to pay for newer guideline-directed medical therapies for heart failure (eg, sacubitril/valsartan, sodium-glucose co-transporter-2 inhibitors)
- Ability/willingness to obtain laboratory monitoring tests (eg, follow-up potassium following initiation of an aldosterone antagonist)
- Emotional status (eg, presence of anxiety, depression)

Plan (see Tables 37-3 to 37-6; Figs. 37-1, 37-3, and 37-4)*

- Drug therapy regimen, including guideline-directed medical therapies for heart failure as well as dose, route, frequency, and duration
- Monitoring parameters for efficacy (eg, weight to maintain euvolemia, surrogate markers of end-organ function) and safety (eg, orthostasis); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug-specific information, medication administration)
- Referrals to other providers when appropriate (eg, electrophysiology for implantable cardioverter-defibrillator [ICD] placement, upgrade of ICD to chronic resynchronization therapy [CRT])

Implement (see Table 37-6)*

- Provide patient education regarding all elements of the treatment plan (eg, self-monitoring of weight, sodium and fluid dietary restriction, self-titration of diuretic dose in select patients)
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up in three to seven days following hospital discharge

Follow-up: Monitor and Evaluate (see Tables 37-1 and 37-6)

- Resolution of symptoms of fluid overload or low cardiac output
- Presence of adverse drug reactions (eg, orthostasis due to over-diuresis or excess vasodilation)
- Obtain relevant laboratory monitoring data (eg, potassium, magnesium, BUN/serum creatinine [diuretics]; BP [eg, sacubitril/valsartan, ACE inhibitor, ARB, β-blocker]; and HR [eg, β-blocker])
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate need for escalation of guideline-directed medical therapy (up-titration or initiation of additional therapies) or referral for nonpharmacologic therapies (eg, ICD, CRT, mitral valve repair) or advanced therapies (eg, ventricular assist device, transplant) every one to three months depending on the severity of illness

**In collaboration with the patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

④ The overall goals of therapy in ADHF evolve over the course of a hospitalization (Fig. 37-3).[3] During the acute phase, the goals are to relieve symptoms, improve hemodynamic stability (ie, restore end-organ perfusion if compromised), and reduce short-term mortality, and address precipitating factors (eg, arrhythmias, hypertension, myocardial ischemia, medication or dietary nonadherence). Other key considerations include evaluating medications (including noncardiac medications) that may worsen cardiac function. Although IV diuretic, vasodilator, and inotropic therapy can be very effective at achieving these short-term goals, their efficacy must be balanced against the potential for serious adverse drug reactions. Decongestion should be prioritized even if it is accompanied by mild to moderate WRF, as failure to relieve congestion prior to discharge increases the risk of rehospitalization and mortality.[14–16] Patients should be routinely evaluated for their progress toward these goals as care may need to be escalated for those whose progress stalls or worsens despite routine therapy. For patients whose course improves with therapy, the focus of care shifts to the optimization of GDMT, patient education, and coordination of care, all of which are critical to preventing rehospitalization and improving survival. When available and appropriate, patients should be referred to an HF disease management program.[2]

FIGURE 37-3

Clinical course of HF hospitalization. Graphic depiction of HF hospitalization, showing the degree of focus on clinical decompensation (red), discharge coordination (blue), ongoing coordination of outpatient care (light blue), and optimization of guideline-directed medical therapy (green), with ongoing assessment of the clinical course (circle with arrows), and key time points for review and revision of the long-term disease trajectory for the HF journey (compass signs). General Approach to Treatment

⑤ An important step in the management of ADHF is to assess medications being taken prior to admission and determine whether adjustment or discontinuation is required. Medications that may cause or contribute to ADHF due to negative inotropic effects (eg, nondihydropyridine calcium channel blockers) or by promoting fluid retention (eg, NSAIDs, mineralocorticoids, thiazolidinediones) should be discontinued. If fluid retention is evident on physical examination, aggressive diuresis should be pursued. The use of IV diuretics is recommended over increased doses of oral diuretics, and the regimen being taken prior to admission should be used to guide initial IV diuretic dosing.[2] In the absence of cardiogenic shock or symptomatic hypotension, every effort should be made to continue all GDMT for HF. β-Blocker therapy may be temporarily held or dose-reduced if recent initiation or up-titration is responsible for acute decompensation. Otherwise, β-blocker discontinuation is discouraged as it worsens outcomes in patients with ADHF.[17,18] Appropriateness of initiating β-blockers prior to discharge will be discussed later in this chapter.

Select GDMT may also need to be temporarily held in the setting of renal dysfunction, especially if oliguria or hyperkalemia is present (eg, ACE inhibitors, angiotensin receptor blockers, angiotensin receptor-neprilysin inhibitors, aldosterone antagonists). Therapies that may cause WRF (eg, ACE inhibitors, angiotensin receptor blockers, angiotensin receptor-neprilysin inhibitors) should only be initiated or up-titrated cautiously during aggressive volume removal with IV diuretic therapy. In addition, serum potassium concentrations should be monitored closely as IV diuretic therapy is transitioned to oral diuretic therapy, especially if an aldosterone antagonist has been initiated during the hospital stay; this ensures therapy can be tolerated on the intended oral diuretic dose prescribed at discharge. Most patients may continue to receive digoxin at doses targeting a trough serum concentration of 0.5 to 0.9 ng/mL (mcg/L; 0.6-1.2 nmol/L).[2] Discontinuation of digoxin is generally discouraged as withdrawal of therapy can worsen HF.[19,20] Digoxin should only be discontinued if serum concentrations cannot be safely maintained within the desirable range (eg, fluctuating renal function) or if patients demonstrate evidence of toxicity.

⑥ The acute management of ADHF is based primarily on hemodynamic status.[2] Patients with underlying HFrEF may present in any of the four hemodynamic subsets, whereas those with HFpEF usually present in subset II. Two general approaches exist for determining hemodynamic status. One is to use simple clinical parameters (eg, signs and symptoms, blood pressure, and organ function), and the other is to use these in conjunction with invasive hemodynamic monitoring. A management algorithm based on the hemodynamic subset is depicted in Fig. 37-1. The hemodynamic effects exerted by pharmacologic therapies used in the management of ADHF are illustrated in Fig. 37-4.

FIGURE 37-4

Hemodynamic effects of pharmacologic therapy in ADHF. Pharmacologic agents used in the management of ADHF exert important effects on cardiovascular hemodynamics. Although diuretics and venodilators reduce preload, this does not substantially reduce cardiac output in patients with heart failure and adequate filling pressures due to a flatter Frank–Starling curve. Arterial vasodilators reduce afterload, producing an increase in cardiac output as a consequence of improved left ventricular performance in patients with reduced ejection fraction. Vasodilators with effects on both venous and arterial tissue may reduce both preload and afterload. Inotropes improve contractility directly, although some agents (eg, milrinone) may exert salutary effects on afterload via vasodilation.

Subset I (Warm and Dry)

Patients in subset I generally do not have signs and symptoms of volume overload or hypoperfusion and usually have CI and PCWP values within appropriate ranges. Patients in this subset have the lowest risk of mortality and do not require immediate intervention other than optimization of GDMT for HF.

Subset II (Warm and Wet)

Patients in subset II are likely to present with signs and symptoms of congestion (eg, orthopnea and peripheral edema) due to increased hydrostatic pressure in the pulmonary and systemic circulation, but without evidence of peripheral hypoperfusion. As a consequence, they often have adequate CO but a PCWP greater than 18 mm Hg. The primary goal of therapy in these patients is to relieve symptoms of congestion by lowering PCWP to an acceptable range (ie, 15-18 mm Hg). Considerably greater reductions should generally be avoided, as these could compromise CO, increase heart rate, or provoke neurohormonal activation.

Intravenous agents that reduce preload via diuresis and/or direct venodilation (eg, loop diuretics) are the most appropriate initial therapy for patients presenting in subset II. Although symptomatic improvement may occur within minutes of IV loop diuretic administration, significant relief of congestive symptoms may require several hours in select patients. Resistance to loop diuretics may occur, requiring dose escalation or addition of thiazide-type diuretics. IV vasodilators with effects on primarily the venous vasculature (eg, nitroglycerin) may be used for rapid venodilation (see Fig. 37-4), which can aid in acutely improving dyspnea. IV vasodilators do not improve outcomes in ADHF beyond dyspnea relief and should therefore be reserved for patients with acute pulmonary edema with respiratory distress or severe hypertension and avoided in patients with low blood pressure. Failure to respond to these therapies may indicate the presence of impaired CO and should prompt a reevaluation of perfusion status (with or without PA catheter insertion).

Patients in subset II should also be placed on a sodium restriction (2-3 g daily). In patients with moderate hyponatremia (<130 mEq/L [mmol/L]) or excess fluid intake that limits effective decongestion, fluid restriction (<2 L daily) should be considered. In patients with worsening or severe hyponatremia (<125 mEq/L [mmol/L]), a stricter fluid restriction may be necessary and an arginine vasopressin (AVP) antagonist may be considered in patients who develop neurologic symptoms.[2] Finally, supplemental oxygen should be administered as needed for hypoxemia (arterial oxygen saturation <90% [0.90]).

Subset III (Cold and Dry)

Patients in subset III present with evidence of peripheral hypoperfusion (eg, weakness, decreased urine output, and weak pulses) but no signs or symptoms of congestion. They often present with a CI of less than 2.2 L/min/m^2 (0.037 L/s/m^2) but no abnormal elevation in PCWP. The mortality rate of patients in subset III is higher than that of patients with adequate perfusion.[21] Although the treatment goal is to alleviate signs and symptoms of hypoperfusion by increasing CI and perfusion to essential organs, therapy may differ based on initial presentation. If evidence of hypovolemia exists (eg, orthostatic hypotension) or PCWP is below 15 mm Hg, IV fluids should be cautiously administered to provide a more optimal left ventricular filling pressure (ie, 15-18 mm Hg), consequently improving CI (see Fig. 37-1). As this presentation most often occurs in the setting of overly aggressive diuresis, diuretic therapy should be withheld and fluid restriction liberalized; these interventions alone may obviate the need for IV fluids.

In patients whose CI remains low despite restoration of optimal left ventricular filling pressures, IV positive inotropic agents (eg, dobutamine and milrinone) and/or IV arterial vasodilators (eg, nitroprusside) may be necessary to achieve adequate CI (see Fig. 37-4). IV inotropes should also be avoided in patients with low left ventricular filling pressure and generally reserved for patients with evidence of severely low CO who are not candidates for IV vasodilators (ie, hypotension). They may also be used to “bridge” patients to MCS or heart transplantation, or as palliative therapy to improve functional status and quality of life in patients who are ineligible for definitive therapies.

Subset IV (Cold and Wet)

Patients in subset IV present with signs and symptoms of both volume overload and peripheral hypoperfusion, and often have a PCWP exceeding 18 mm Hg and a CI of less than 2.2 L/min/m^2(0.037 L/s/m^2). This subset is characterized by the worst prognosis of all four and represents the most common hemodynamic profile for patients with end-stage HF. Given the severity of HF, patients in subset IV cannot maintain adequate CI despite elevated left ventricular filling pressure and increased myocardial fiber stretch. Treatment goals for these patients include alleviation of signs and symptoms of congestion and hypoperfusion by increasing CI to above 2.2 L/min/m^2 (0.037 L/s/m^2) and reducing PCWP to 15 to 18 mm Hg while maintaining adequate MAP. Therapy often involves a combination of agents used in subsets II and III (ie, a combination of IV diuretic plus vasodilator or inotrope). These targets may be difficult to achieve and often necessitate careful monitoring and individualization of drug therapy. In the presence of significant hypotension and low MAP (and SVR is low to normal or unknown), vasodilators should be avoided. In some cases, even the vasodilating effects of inotropic therapy may compromise MAP, requiring that combined inotrope and vasopressor therapy (eg, dobutamine plus norepinephrine) or an inotrope with vasopressor activity (eg, dopamine) be used to achieve adequate end-organ perfusion. Once end-organ perfusion and hemodynamic stability have been restored, therapy can then be adjusted to obtain the desired clinical response (see Fig. 37-1).

Pharmacologic Therapy

Despite advances in the care of patients with HF, none of the therapies used in the treatment of ADHF confer long-term improvements in morbidity and mortality, and some may cause harm when used indiscriminately (eg, IV inotropes). Therefore, the primary role of pharmacologic therapy in ADHF is to relieve acute symptoms and stabilize patients so that GDMT may be safely initiated or titrated.

Loop Diuretics

⑦ The IV loop diuretics furosemide and bumetanide are the mainstay of therapy for relieving congestion in the setting of ADHF (Table 37-3); furosemide remains the most widely studied and used in this setting.[22] Bolus administration reduces preload within 5 to 15 minutes by functional venodilation and later (>20 minutes) via sodium and water excretion, thereby improving pulmonary congestion. Although patients with HFrEF can tolerate significant reductions in preload without compromising stroke volume, excessive diuresis (ie, PCWP <12 mm Hg or CVP <3 mm Hg) can lead to a decline in CO (see Fig. 37-4). Excessive or rapid reductions in preload may also compromise CO in patients with preload-dependent conditions (eg, aortic stenosis, hypertrophic obstructive cardiomyopathy, restrictive or constrictive cardiomyopathies, right ventricular failure, or severe diastolic dysfunction) or if diuresis exceeds the rate at which fluid can migrate from the interstitial space back into the systemic vasculature (ie, transcapillary refill rate). One scenario in which the latter may occur is with reduced oncotic pressure resulting from hypoalbuminemia, which is common in patients with advanced HF who become malnourished due to early satiety (as a consequence of abdominal edema and/or reduced perfusion to the GI tract). Patients with these conditions often require less aggressive decongestion goals (eg, net negative 1 L per day, or an amount of urine output that is approximately 1 L more than all of the fluid taken in over the course of a day).

TABLE 37-3

Diuretics Commonly Used for the Management of ADHF

Loop Diuretics			
Characteristic	**Furosemide**	**Bumetanide**	
Oral bioavailability	10-100% (mean 50%)	80-90%	
Dose equivalence (IV)[a]	20-40 mg	1 mg	
Usual intermittent bolus dose (maximum)[b]	40-160 mg (200-300 mg)	1-4 mg (6-8 mg)	
Usual infusion rate (maximum)[b]	10-20 mg/hr (40-80 mg/hr)	0.5 mg/hr (2-4 mg/hr)	
Duration of action	4-6 hours	4-6 hours	
Thiazide-Type Diuretics			
Characteristic	**Metolazone**	**Chlorothiazide**	**Hydrochlorothiazide**
Usual dose (maximum)[b]	2.5-5 mg orally once daily (20 mg/day)	500 mg IV twice daily (2000 mg/day)	50 mg orally once daily (200 mg/day)
Duration of action	12-24 hours	6-12 hours	5-15 hours
Other considerations	Oral absorption is erratic and delayed. No evidence of superiority to other thiazides but is most commonly used.	Oral formulations have poor absorption and should not be used. More costly but no evidence of superiority over other thiazides.	Higher doses than those used for hypertension are typically required to facilitate diuresis.

IV, intravenous.

[a] Torsemide is currently unavailable in an intravenous formulation, but its IV dose equivalence is 20 mg.

[b] Some institutions have published experience with higher doses; the ranges and maximum doses listed may be exceeded if the benefits justify the risks.

Unlike arterial vasodilators and positive inotropic agents, diuretics do not cause an upward shift in the Frank–Starling curve or significantly increase CO in most patients (see Fig. 37-4). In some cases, patients with severe congestion may experience improvements in CO as PCWP approaches the normal range (see Fig. 37-4), which may explain why renal function occasionally improves in the setting of diuresis. Alternatively, improvements in renal function may reflect the relief of congestive nephropathy.

IV loop diuretics are recommended as first-line therapy for patients with ADHF and volume overload.[2] Although the oral bioavailability of loop diuretics is relatively unchanged in patients with HF who have adequate GI perfusion, the rate of absorption is prolonged by approximately twofold and peak concentrations are reduced by approximately half. Because loop diuretics have a sigmoidal-shaped concentration–response curve, prolonged absorption may result in concentrations that fail to reach the threshold necessary for producing diuresis, necessitating the use of IV therapy.

Low doses (ie, doses equivalent to IV furosemide 20-40 mg) once to twice daily should initially be selected in patients with ADHF who are naïve to loop diuretics. For patients taking loop diuretics prior to admission, a total daily dose of 1 to 2.5 times their home dose is recommended.[2,22] Higher doses are associated with more rapid relief of congestive symptoms but may also mildly increase the risk of transient worsening of renal function (WRF).[22,23]

Once an initial total daily dose is determined from the home diuretic regimen, doses may be administered as either an IV bolus (ie, divided every 12 hours) or continuous IV infusion.[2] Although major differences in relief of congestive symptoms, weight loss, or long-term outcomes have not been observed between these two methods of administration, a greater natriuretic effect may occur when the same total daily dose is administered as a continuous infusion rather than an IV bolus.[22–24] Given limitations in the designs of published trials, the appropriate method of administration for loop diuretic therapy in ADHF remains an area of controversy.[25,26]

Subsequent doses of loop diuretic therapy should be adjusted to patient response, as determined by urine output, weight loss, or urine sodium concentrations (goal >70 mEq/L [mmol/L]). Most patients tolerate at least a 2-L per day net negative diuresis (or a 2-kg weight loss), but diuretic therapy must be highly individualized in order to obtain the desired improvement in congestive symptoms while avoiding a reduction in CO, symptomatic hypotension, or WRF. Importantly, WRF alone should not be interpreted as evidence of euvolemia or as a reason to discontinue diuretics, as at least mild to moderate WRF occurs in approximately half of patients with ADHF.[22,27] The prognostic significance of WRF is strongly associated with the etiology of injury and among patients achieving decongestion with diuresis, WRF is not indicative of renal tubular injury or a worsened prognosis.[16,27,28] Therefore, careful evaluation of the patient's volume status and clinical context should guide decisions about diuretic therapy and GDMT (eg, ACE inhibitors, angiotensin receptor blockers, sacubitril/valsartan). Invasive hemodynamic monitoring can also be used to confirm volume status when the appropriate next steps are unclear based on changes to physical examination or laboratory findings. Finally, electrolyte depletion (eg, potassium, magnesium) should also be monitored daily at minimum and more frequently when high doses or combination diuretic therapy is used.

Strategies to Overcome Diuretic Resistance

Occasionally, patients respond inadequately to appropriate doses of loop diuretics, a phenomenon subjectively referred to as diuretic resistance. Unfortunately, attempts to define diuretic resistance in quantitative terms have not resulted in clinically applicable measures, and the mechanisms responsible for diuretic resistance are diverse.[29] However, the predominant mechanisms of diuretic resistance are intra-renal, specifically diminished diuretic response in the loop of Henle, and compensatory sodium reabsorption in the distal convoluted tubule.[29] Over time, the distal tubule may also undergo hypertrophy, thereby enhancing its ability to reabsorb sodium. Impaired CO resulting in reduced renal perfusion is an infrequent contributor to diuretic resistance, thus IV inotropic therapy should only be used to treat diuretic resistance if patients are in hemodynamic subset IV (ie, cold and wet).

Diuretic resistance is primarily treated by increasing the doses of loop diuretics or augmenting them by adding a diuretic with an alternative mechanism of action (eg, thiazide-type diuretics).[2] Although an escalation of loop diuretics should be prioritized due to an increased risk of adverse events with combination diuretic therapy, no consensus exists regarding the dose at which alternative diuretics should be added.[29,30] Given the sigmoidal dose–response curve of loop diuretics, a doubling of the dose is required to improve diuresis. Bolus doses should be increased if an inadequate response is not observed within six hours and the frequency of dosing should be increased if a response is observed but patients still fail to meet overall diuresis goals. Transitioning to continuous infusion loop diuretics may also be considered provided it is accompanied by a substantial increase in the total daily dose, although studies comparing this approach to IV bolus administration in patients with diuretic resistance have not been performed.

For patients with refractory congestion despite increased doses of loop diuretics, adding a distal tubule blocker such as oral metolazone, oral hydrochlorothiazide, or IV chlorothiazide (Table 37-3) can produce a synergistic diuretic effect.[2] Inhibition of sodium reabsorption in the loop of Henle increases sodium delivery to (and reabsorption in) the distal convoluted tubule, which can be subsequently blocked by a thiazide-type diuretic. When added to loop diuretics, IV chlorothiazide and oral metolazone are similarly efficacious and safe, as the higher potency and longer duration of metolazone likely compensate for its erratic absorption and delayed onset of action.[31] Sequential nephron blockade with a loop and thiazide-type diuretic should generally be reserved for hospitalized patients, as profound diuresis with severe electrolyte and intravascular volume depletion may occur. Patients should also receive close follow-up (eg, weight, vital signs, serum potassium, and assessment for orthostatic hypotension) to avoid serious adverse events.

Several other pharmacologic strategies have been investigated for relieving congestion or overcoming diuretic resistance in ADHF.[32] Studies are currently underway to investigate the addition of acetazolamide, a carbonic anhydrase inhibitor, to loop diuretics in patients with ADHF. On the basis of their benefits in patients with chronic HFrEF, sodium-glucose cotransporter-2 (SGLT2) inhibitors are also being explored for their diuretic and natriuretic effects in patients with ADHF. One strategy for enhancing diuresis that has fallen out of favor is the administration of low doses of dopamine (ie, 2-5 mcg/kg/min), as this approach does not consistently improve congestive symptoms or diuresis and it increases the risk of tachyarrhythmias.[33,34] Given the evidence of β-mediated effects at lower infusion rates, dopamine likely does not provide any advantages over a traditional inotrope when used in this setting.

Vasopressin Antagonists

Vasopressin receptor antagonists have been extensively studied in ADHF, particularly when complicated by severe hyponatremia, which is commonly defined as a serum sodium concentration of less than 125 mEq/L (mmol/L). Heart failure is most commonly associated with hypervolemic hyponatremia and is often characterized by inappropriately elevated concentrations of AVP or antidiuretic hormone. In the setting of HF, reduced CO leads to excess stimulation of arterial baroreceptors, which in turn enhances AVP secretion and consequently, stimulation of vasopressin receptors. Of particular importance in ADHF are V_2 receptors, which are located in the renal tubules, where stimulation by AVP results in net water reabsorption.

Although the prevalence of hyponatremia in patients with HF varies by the serum sodium threshold used, as many as one in five patients hospitalized with ADHF present with serum sodium concentrations less than 136 mEq/L (mmol/L).[35] Furthermore, the presence of hyponatremia has been associated with increased mortality in this population.[36]

Most cases of hyponatremia are mild, asymptomatic, and self-limited, but prompt diagnosis and management is critical for the less common but life-threatening presentation, which may include lethargy, confusion, respiratory arrest, cerebral edema, seizures, coma, or death. Because vasopressin antagonists have failed to improve outcomes in ADHF beyond increases in serum sodium concentrations and marginal improvements in urine output and congestive symptoms, their role is limited to the treatment of severe hyponatremia.[2,37,38]

The two currently available vasopressin receptor antagonists are tolvaptan and conivaptan. Tolvaptan selectively binds to and inhibits the V_2 receptor, whereas conivaptan nonselectively inhibits both V_{1A} and V_2 receptors. Stimulation of V_{1A} receptors in vascular smooth muscle and myocardium results in vasoconstriction, myocyte hypertrophy, and positive inotropic effects, but the clinical consequences of inhibiting these effects with conivaptan are unknown. Conivaptan is an IV agent indicated for hypervolemic and euvolemic hyponatremia resulting from a variety of causes, but because it is not indicated in patients with ADHF, its use will not be discussed in further detail here.

Tolvaptan is orally bioavailable and indicated for the management of hypervolemic and euvolemic hyponatremia in patients with SIADH, cirrhosis, or HF. It is typically initiated at 15 mg daily and then titrated to 30 mg or 60 mg as needed for resolution of hyponatremia (ie, typically no longer than several days to a week). Importantly, tolvaptan is a substrate of cytochrome P450 3A4 and is contraindicated with potent inhibitors of this enzyme. Patients receiving vasopressin antagonists must be monitored closely to avoid an overly rapid rise in serum sodium (>12 mEq/L [mmol/L] per 24 hours); fluid restrictions should be liberalized to reduce this risk.

Vasodilators

⑨ Current guidelines focus on the role of IV vasodilators as an adjunct treatment for refractory congestive symptoms,[2] but they may also be helpful for restoring tissue perfusion in select patients with low CO. Vasodilators are commonly classified according to their most prominent site of action (ie, arterial or venous circulation). As described in the section on patients in subset II, venodilators act as preload reducers by increasing venous capacitance, thus reducing symptoms of pulmonary congestion in patients with high ventricular filling pressures. Arterial vasodilators exert their beneficial effects by counteracting the peripheral vasoconstriction and impaired CO that can result from the activation of the sympathetic nervous system, renin–angiotensin–aldosterone system, and other neurohormonal mediators in both acute and chronic HF. In these patients, arterial vasodilators act as impedance-reducing agents, reducing afterload and causing a reflexive improvement in left ventricular performance and thus an increase in CO. Mixed vasodilators act on both resistance and capacitance vessels, reducing congestive symptoms while increasing CO.

Intravenous vasodilators should, therefore, be considered prior to positive inotropic therapy in patients with low CO and elevated SVR (or elevated blood pressure in those without a PA catheter). For patients in whom blood pressure or SVR is already low, including those receiving GDMT with vasodilating effects (eg, ACE inhibitors) or those with advanced HF, hypotension may preclude the use of IV vasodilators. In patients with advanced HF and limited contractile reserve, increases in left ventricular performance may not fully compensate for reductions in afterload, leading to worsening hypotension. In addition, IV vasodilators have not been extensively studied in patients with HFpEF, where a sudden drop in preload may compromise existing defects in ventricular filling, leading to decreased CO.[39]

The most commonly used IV vasodilators in ADHF are nitroglycerin and sodium nitroprusside, which differ according to their effects on arterial and venous circulation (Table 37-4). Nitroglycerin is primarily a venodilator (except at high doses) whereas sodium nitroprusside is a mixed venous and arterial vasodilator. Once stabilized on IV therapies, transitioning to oral vasodilators (eg, nitrates/hydralazine, ACE inhibitors) should be considered.

TABLE 37-4

Vasodilators Commonly Utilized for the Management of ADHF[a]

Drug (Vasodilatory effect)	Onset, Half-life	Elimination	Dose	HR	MAP	PCWP	CO[b]	SVR
Nitroglycerin (venous > arterial)	Immediate, <4 mins	Inactive metabolites in urine	10-20 mcg/min and titrate 10-20 mcg/min q10–20 mins, max 200 mcg/kg/min	0/↑	0/↓	↓	0/↑	0/↓
Nitroprusside (venous = arterial)	Immediate, 2 mins	Cyanide (hepatic), thiocyanate (renal)	0.1-0.2 mcg/kg/min, titrate 0.1-0.2 mcg/kg/min q10-20 mins, max 3 mcg/kg/min	0/↑	0/↓	↓	↑	↓
Furosemide (venous only)	1 hr (PO)/ 5 mins (IV), 2 hrs	Urine	Variable[c]	0	0/↓	↓	0	0
Isosorbide dinitrate (venous only)	1 hr, 2-5 hrs for active metabolites	Hepatic	10-60 mg q8h	0/↑	0	↓	0	0
Hydralazine (arterial only)	1-2 hrs (PO), 3-7 hrs	Hepatic	12.5-100 mg q6–8h	0/↑	0/↓	0	↑	↓
Captopril (arterial > venous)	<15 mins, 2-4 hrs	Urine	6.25-50 mg q8h	0	0/↓	↓	↑	↓

[a] See text for a more detailed description of the interpatient variability in response.

[b] Indirect effects due to decreased arterial impedance.

[c] Intravenous bolus administered <0.4 mg/min.

↑, increase; ↓, decrease; 0, no change; HR, heart rate; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; CI, continuous infusion; CO, cardiac output; IVB, intravenous bolus; SVR, systemic vascular resistance.

Nitroglycerin

Intravenous nitroglycerin is often preferred for preload reduction in patients with ADHF, especially those requiring urgent relief of dyspnea (ie, acute pulmonary congestion). Because of its short half-life (1-3 minutes), IV nitroglycerin is administered by continuous infusion. Its major hemodynamic effects are reductions in preload and PCWP via functional venodilation and mild arterial vasodilation that is particularly evident in patients with HF and elevated SVR or when given in doses exceeding 100 mcg/min (see Table 37-4).[40] At higher doses, nitroglycerin displays potent coronary vasodilating properties, exerting beneficial effects on myocardial oxygen demand and supply and making it the vasodilator of choice for patients with severe HF and ischemic heart disease.

Nitroglycerin should be initiated at a dose of 5 to 10 mcg/min (0.1 mcg/kg/min) and increased every 5 to 10 minutes as tolerated. Hypotension and an excessive decrease in PCWP are important dose-limiting adverse drug reactions. Maintenance doses usually vary from 35 to 200 mcg/min (0.5-3 mcg/kg/min). While tolerance to the hemodynamic effects of nitroglycerin may develop within hours of continuous administration, some patients experience a sustained response; this variability in response to nitroglycerin requires that patients be continuously monitored (eg, symptoms, hemodynamic parameters) to guide adjustments to therapy. Nitroglycerin should not be used in the presence of elevated intracranial pressure because it may worsen cerebral edema in this setting.

Sodium Nitroprusside

As a result of its balanced effects in arterial and venous tissue, sodium nitroprusside increases CI to a similar degree as dobutamine and milrinone despite having no direct inotropic activity; however, greater decreases in PCWP, SVR, and blood pressure are generally observed. MAP may remain fairly constant due to reflexive improvements in stroke volume and CO but can decrease based on the extent of arterial smooth muscle relaxation. Patients with normal left ventricular function do not experience an increase in stroke volume when SVR falls because the normal ventricle is fairly insensitive to changes in afterload. Consequently, these patients may experience a significant decrease in blood pressure in response to arterial vasodilators. These differences explain why sodium nitroprusside is a potent antihypertensive agent in patients without HF but causes less hypotension and reflex tachycardia in the presence of left ventricular dysfunction (see Fig. 37-2). Nonetheless, hypotension remains an important dose-limiting effect of sodium nitroprusside, and its use should be primarily reserved for patients with elevated SVR. Close monitoring of therapy is warranted, as even modest increases in heart rate can have adverse consequences in patients with underlying ischemic heart disease and/or resting tachycardia.

Sodium nitroprusside is an effective strategy for the short-term management of patients with acute HF across a variety of settings (eg, acute MI, valvular regurgitation, postcoronary bypass surgery, and ADHF). Generally, sodium nitroprusside does not worsen, and may even improve, the balance between myocardial oxygen demand and supply by lowering both left ventricular wall tension (thus reducing oxygen demand) and end-diastolic pressure (thereby increasing subendocardial blood flow). However, an excessive decrease in systemic arterial pressure may reduce coronary perfusion and worsen ischemia due to coronary steal. Consequently, therapy should be avoided in patients with recent MI in the absence of persistent congestive symptoms or elevated ventricular filling pressures.[41] In ADHF specifically, sodium nitroprusside improves low CO and may support the initiation and titration of GDMT, even among patients with lower MAP (<85 mmHg).[42]

Sodium nitroprusside has a rapid onset of action, but its effects last less than 10 minutes, necessitating administration by continuous IV infusion. Its short duration of action also allows precise dose-titration based on clinical and hemodynamic response. As with nitroglycerin, sodium nitroprusside should be initiated at low doses (0.1-0.2 mcg/kg/min) to avoid excessive hypotension and increased by small increments (0.1-0.2 mcg/kg/min) every 5 to 10 minutes as tolerated. Effective doses usually range from 0.5 to 3 mcg/kg/min. A rebound phenomenon, which may be due to reflex neurohormonal activation during sodium nitroprusside therapy, has been reported following abrupt withdrawal in patients with HF. Therefore, therapy should be tapered slowly when transitioning patients to oral medications. As with nitroglycerin, sodium nitroprusside should be avoided in the presence of elevated intracranial pressure as it may worsen cerebral edema in this setting.

Following IV administration, sodium nitroprusside interacts with hemoglobin to release cyanide, which undergoes hepatic conversion to thiocyanate before it is eliminated renally. As a consequence, sodium nitroprusside can cause cyanide and thiocyanate toxicity, but these effects are unlikely when doses less than 3 mcg/kg/min are administered for less than 3 days, except in patients with significant renal impairment (ie, serum creatinine concentration >3 mg/dL (265 µmol/L). Closer monitoring for signs and symptoms of toxicity (eg, altered mental status, nausea or vomiting, metabolic acidosis) should be considered in patients with renal impairment or when higher doses or prolonged durations of sodium nitroprusside must be used.

Inotropes

⑩ Patients in subsets III and IV ("cold" subsets) require prompt correction of low CO in order to restore peripheral tissue perfusion and preserve end-organ function. Although IV inotropes can improve peripheral hypoperfusion by directly enhancing cardiac contractility, their association with adverse outcomes (eg, arrhythmias, in-hospital mortality) necessitates that they are reserved for select patients with refractory ADHF, particularly those unable to tolerate vasodilators due to hypotension.[43] Inotrope therapy should be considered only as a temporizing measure for maintaining end-organ perfusion in patients with cardiogenic shock or evidence of severely depressed CO and low systolic blood pressure (ie, ineligible for IV vasodilators) until definitive therapy can be initiated, as a "bridge" for those with advanced HF who are eligible for MCS or cardiac transplantation, or for palliation of symptoms in patients with advanced HF who are not eligible for MCS or cardiac transplantation.[2]

Patients in these latter two groups may require placement of an indwelling IV catheter for continuous outpatient administration of inotropic therapy.

Palliative use of IV inotropes should only be considered after multiple unsuccessful attempts have been made to wean therapy and maximize GDMT, as the risk of mortality is likely increased with IV inotrope use.

Importantly, IV inotropes rarely, if ever, produce a single cardiovascular action. Even when intended for a specific purpose (eg, positive inotropic effects), other cardiovascular effects (tachycardia, vasodilation, or vasoconstriction) may either add to the therapeutic effect of the drug or cause adverse drug reactions that negate or even outweigh its intended therapeutic benefit. How an individual patient will respond to an intervention is often difficult to anticipate. For this reason, hemodynamic monitoring with a PA catheter may be useful.

The two IV inotropic agents most commonly used for the management of ADHF are dobutamine and milrinone. Although both drugs increase intracellular concentrations of cAMP, they do so by different mechanisms. Dobutamine activates adenylate cyclase through direct stimulation of β-adrenergic receptors, thus catalyzing the conversion of adenosine triphosphate to cAMP, whereas milrinone reduces degradation of cAMP by inhibiting phosphodiesterase type 3. Increased intracellular cAMP enhances phospholipase (and subsequently phosphorylase) activity, increasing the rate and extent of calcium influx during systole and thus enhancing contractility. In addition, cAMP enhances the reuptake of calcium by the sarcoplasmic reticulum during diastole, improving active relaxation (ie, positive lusitropic effects). Comparisons between dobutamine and milrinone indicate that the two agents generally produce similar hemodynamic effects, although dobutamine is usually associated with more pronounced increases in heart rate and milrinone is associated with greater relaxation in arterial smooth muscle. Differences in the pharmacologic effects of the two agents may confer advantages or disadvantages in an individual patient; these and other clinical considerations for their use in the management of ADHF will be reviewed in the sections to follow.

Digoxin rarely has a role in hemodynamically unstable patients due to its limited inotropic effects. In patients who take digoxin as chronic therapy, discontinuation or dose-adjustment during an acute decompensation is generally unnecessary unless changes in renal function increase the risk of toxicity. As discussed previously in this chapter, discontinuation should be discouraged in the absence of toxicity, given the potential for digoxin withdrawal.[19,20]

Dobutamine

The receptor activities of dobutamine and other adrenergic agonists are summarized in Table 37-5. Dobutamine, a synthetic catecholamine, is a β_1- and β_2-receptor agonist with some α_1-agonist effects. Because dobutamine does not cause the release of norepinephrine from nerve terminals, its positive inotropic effects are attributed to its action on β_1-receptors. Stimulation of cardiac β_1-receptors by dobutamine does not generally produce a significant change in heart rate, thus explaining its modest chronotropic effects. Modest peripheral β_2-receptor-mediated vasodilation tends to offset minor α_1-receptor-mediated vasoconstriction. In addition, the increase in CO often results in a reflexive decline in SVR. As a consequence, the net hemodynamic effect of dobutamine, particularly at low doses, is usually vasodilation.

TABLE 37-5

Inotropes Commonly Used for the Management of ADHF[a]

Drug	Onset, Half-life	Dose	Receptor Affinity ($\alpha_1/\beta_1/\beta_2$)	HR	MAP	PCWP	CO	SVR
Dobutamine	<10 mins, 2 mins	1-2 mcg/kg/min, titrate 1-2 mcg/kg/min q10–20 mins, max 20 mcg/kg/min	↑/↑↑↑↑/↑↑	0/↑	0	↓	↑	0/↓
Milrinone	5-15 min, 1-4 hr, (prolonged if renal dysfunction)	0.1-0.2 mcg/kg/min, titrate 0.1 mcg/kg/min q4–16 hrs (titrate slowly in renal dysfunction), max 0.75 mcg/kg/min (IVB dose generally avoided)	Phosphodiesterase inhibition	0/↑	0/↓	↓	↑	↓

[a] See text for a more detailed description of the dose-dependent hemodynamic effects.

The effects of dobutamine are observed within minutes, but its peak effects may take up to 10 minutes to occur. Initial doses of 2.5 to 5 mcg/kg/min may be adjusted based on clinical and hemodynamic responses. Although doses of up to 20 mcg/kg/min are occasionally used, most patients are maintained at doses of 7.5 mcg/kg/min or less. The cardiac index is increased due to inotropic stimulation, arterial vasodilation, and a variable increase in heart rate. Because of offsetting changes in arteriolar resistance and CI, dobutamine usually causes relatively little change in MAP, unlike the more consistent increases observed with vasopressors. Although its impact on heart rate is variable, the major adverse drug reactions of dobutamine are tachycardia and ventricular arrhythmias. Potentially detrimental increases in oxygen consumption have also been observed. While concerns exist regarding the attenuation of its effects during prolonged administration, changes in receptor expression require that dobutamine be slowly tapered rather than abruptly discontinued.

Milrinone

Milrinone is a bipyridine derivative that inhibits phosphodiesterase 3, an enzyme responsible for the breakdown of cAMP to adenosine monophosphate (AMP). Because both inotropic and vasodilating effects contribute to its therapeutic effects in ADHF, milrinone is often referred to as an inodilator. The relative balance of these pharmacologic effects may vary with dose and underlying cardiovascular pathology.

During IV administration, milrinone produces an increase in stroke volume (and therefore CO) with minimal change in heart rate (see Table 37-5). Despite an increase in CI, MAP may remain constant due to a concomitant decrease in arteriolar resistance. However, the vasodilating effects of milrinone may predominate, leading to a decrease in blood pressure and reflex tachycardia. As such, milrinone should be used cautiously in severely hypotensive patients because it does not increase, and may even decrease, arterial blood pressure.

The half-life of milrinone is about one hour but may be as long as 3 to 6 hours in patients with renal dysfunction. The longer elimination half-life of milrinone presents several disadvantages in patients with ADHF, including the inability to perform minute-to-minute titrations based on hemodynamic changes and persistence of adverse drug reactions (eg, arrhythmias or hypotension) following drug discontinuation. Although a loading dose is still listed in the product labeling for milrinone (50 mcg/kg administered over 10 minutes), this practice is uncommon due to an increased risk of hypotension.[44] Most patients are started on a maintenance infusion of 0.1 to 0.3 mcg/kg/min (up to 0.75 mcg/kg/min). Milrinone is excreted unchanged in the urine, and thus its infusion rate should be decreased by 50% to 70% in patients with significant renal impairment.

The most notable adverse drug reactions associated with milrinone are arrhythmia, hypotension, and thrombocytopenia. Although the incidence of thrombocytopenia is rare, patients should still have platelet counts measured before and during therapy.

Inotrope Selection

Although outcomes are similar between dobutamine and milrinone in patients with cardiogenic shock, certain characteristics may make one agent more ideal in an individual patient.[45] Dobutamine should be considered when a significant decrease in MAP might further compromise hemodynamic function, as this is more common with the initiation of milrinone. The selection of an inotropic drug should also consider whether patients are receiving chronic β-blocker therapy and whether a β_1-selective agent (eg, metoprolol succinate) or mixed α, β-blocking agent (eg, carvedilol) is used. Traditionally, milrinone has been advocated in patients who are receiving chronic β-blocker therapy because its inotropic effects do not involve β-receptor stimulation. However, the hemodynamic effects of dobutamine may persist in the presence of β-blocker therapy, particularly with β_1-selective agents as a result of β-receptor upregulation or selective activation of β_2-receptors by dobutamine.[46] Similar effects are not observed in the presence of carvedilol, which may inhibit the hemodynamic benefits of dobutamine entirely. Concomitant carvedilol therapy may augment the hemodynamic effects of milrinone based on studies with a structurally similar phosphodiesterase inhibitor, enoximone.[46]

The combination of dobutamine and milrinone is likely to produce additive effects on CO and PCWP, suggesting that this regimen may be considered in patients who have dose-limiting adverse drug reactions with either drug class. However, whether this combination provides a therapeutic advantage over the combined use of a positive inotrope and a traditional vasodilator (eg, sodium nitroprusside) is unclear.

Agents with Combined Inotropic and Vasopressor Activity

Although therapies that can increase SVR are generally avoided in ADHF, agents with combined inotropic and vasopressor activity, such as norepinephrine or dopamine, may be required in select scenarios where marked systemic hypotension may preclude the use of traditional IV inotropes (eg, mixed shock, refractory cardiogenic shock). Alternatively, these agents may be used in combination with traditional inotropes so that adjustments can be made to each agent independently to achieve the desired hemodynamic response. Although these strategies are common in clinical practice, minimal data exist to support their use.

Norepinephrine is an endogenous catecholamine that exerts its hemodynamic effects via direct stimulation of α_1- and β_1-adrenergic receptors. Its effects on β_1-adrenergic receptors in myocardial tissue are thought to confer improvements in CO because of increases in heart rate and cardiac contractility. However, despite having a similar affinity for α_1- and β_1-adrenergic receptors, enhanced vasoconstriction via activation of peripheral α_1-receptors appears to be the predominant hemodynamic effect observed clinically. The limited impact of norepinephrine on CO may be due to its lack of affinity for β_2-receptors, which would both enhance cardiac contractility and balance its effects on α_1-receptors in vascular smooth muscle. The affinity of norepinephrine for adrenergic receptors does not appreciably differ based on dose.

Dopamine is an endogenous precursor of norepinephrine and exerts its effects by directly stimulating adrenergic receptors as well as causing the release of norepinephrine from adrenergic nerve terminals. In contrast with norepinephrine, dopamine produces dose-dependent hemodynamic effects because of its relative affinity for α_1-, β_1-, β_2-, and D_1- (vascular dopaminergic) receptors (see Table 37-5). The positive inotropic effects of dopamine are mediated primarily by β_1-receptors and become more prominent at doses of 2 to 5 mcg/kg/min. The cardiac index is increased because of an increase in stroke volume and a variable increase in heart rate, which is also partially dose-dependent. Minimal changes in SVR occur, presumably because neither vasodilation (D_1- and β_2-receptor-mediated) nor vasoconstriction (α_1-receptor-mediated) predominates. However, at doses between 5 and 10 mcg/kg/min, chronotropy and α1-receptor-mediated vasoconstriction become more prominent. MAP is usually raised because of increases in both CI and SVR (see Table 37-5).

Epinephrine is also an endogenous catecholamine that exerts its hemodynamic effects via direct stimulation of α_1-, α_2-, and β_1-adrenergic receptors. Similar to dopamine, epinephrine exerts dose-dependent hemodynamic effects, including increased selectivity for β_1-adrenergic receptors at lower doses (i.e., 0.01-0.05 mcg/kg/min) whereas increased α-adrenergic activity is seen at higher doses (i.e., >0.5 mcg/kg/min).

The vasoconstriction observed with higher doses of norepinephrine and dopamine may limit improvements in CI by concomitantly increasing afterload and preload. Consequently, they should generally be reserved for patients with low CO and low systolic blood pressure despite adequate ventricular filling pressures, or as an adjunct to inotrope therapy when hypotension precludes the use of inotrope therapy alone. At higher doses, agents with vasopressor activity may alter several parameters that increase myocardial oxygen demand (eg, increased heart rate, contractility, and systolic pressure) and potentially decrease myocardial blood flow (eg, coronary vasoconstriction and increased wall tension), which may worsen ischemia in patients with coronary artery disease. As with dobutamine and milrinone, arrhythmogenesis is also more common at higher doses, although this risk appears to be greater with dopamine than with norepinephrine.[47]

Nonpharmacologic Therapy

Several nonpharmacologic therapies are routinely used in ADHF. All patients with congestive symptoms should be placed on a sodium restriction. Given a complex relationship between sodium restriction and ADHF outcomes, no consensus exists on an appropriate sodium limit. For example, intense targets (<0.8 g/day) do not improve outcomes in ADHF, and higher levels of sodium intake (including the administration of hypertonic saline) may counterintuitively improve diuresis in select patients.[48,49] Based on these uncertainties, a general range of <2-3 g daily) is recommended for most patients with ADHF.[2] Fluid restriction should also be considered for those with refractory symptoms. Noninvasive ventilation may be considered in patients with respiratory distress due to acute pulmonary edema, particularly those at risk for intubation. Although most patients with limited mobility should receive pharmacologic thromboprophylaxis with unfractionated heparin or low-molecular-weight heparin, mechanical thromboprophylaxis with intermittent pneumatic compression devices may be considered in patients at high risk for bleeding complications.

Most of the nonpharmacologic therapies used in ADHF are primarily reserved for patients who have failed pharmacologic therapy. Ultrafiltration and wireless invasive hemodynamic monitoring (W-IHM) may be used in the management of congestive symptoms whereas MCS (temporary or durable devices) and cardiac transplantation may be considered in those with advanced disease.[2]

Ultrafiltration

⑧ Renal impairment is common among patients with ADHF, and advanced forms may warrant the use of renal replacement therapy (eg, hemodialysis, ultrafiltration). Ultrafiltration involves the circulation of blood through a high-pressure circuit, where plasma water is removed from whole blood via a semipermeable membrane. Hemodialysis also involves the use of a semipermeable membrane, but water and solutes (eg, electrolytes, toxins) are removed via diffusion as a result of concentration differences between blood and dialysate (a fluid mixture that runs countercurrent to blood flow on the other side of the membrane). As a result of its mechanism of action, ultrafiltration reduces PCWP without adversely affecting hemodynamics or serum electrolyte concentrations.

Ultrafiltration has emerged as an effective strategy for fluid removal in patients with ADHF (up to 500 mL/h), but it is not superior to adequate doses of diuretic therapy and also increases the risk of adverse events.[50–52] Complications of ultrafiltration include those associated with central venous access (eg, infection), adverse effects from the use of IV heparin (to prevent thrombosis of the access line), and intravascular volume depletion, which increases the risk of WRF. Taken altogether, ultrafiltration should generally be reserved for patients demonstrating diuretic resistance despite optimal diuretic therapy, severe renal impairment following diuretic administration, or continued renal impairment despite inotropic therapy.

Wireless Implantable Hemodynamic Monitoring

Increases in cardiac filling pressures often precede the development of congestive symptoms, and W-IHM has recently emerged as a strategy for using early hemodynamic changes to adjust therapy and thus prevent ADHF in high-risk patients.[53] The CardioMEMS Heart Failure System (Abbott; Lake Bluff, IL) consists of a wireless sensor implanted into the PA during a right heart catheterization and an electronic capturing system that collects information on PA systolic, diastolic, and mean pressures. In addition to guiding therapy adjustments during acute hospitalization, W-IHM can also be telemonitored after patients are discharged from the hospital, permitting further titration of diuretic therapy and GDMT. Despite decreasing the risk of HF hospitalization, widespread use of W-IHM has been limited due to concerns regarding the long-term durability and cost-effectiveness of the device.

Temporary MCS

⑪ For patients with refractory ADHF, temporary MCS may be considered for hemodynamic stabilization until the underlying etiology of cardiac dysfunction resolves or has been corrected (“bridge to recovery”) or until evaluation for definitive therapy (eg, durable MCS or cardiac transplantation) can be completed (“bridge to decision”).[2] Due to the invasive nature of MCS and its potential complications, therapy should be reserved for patients who are refractory to maximally tolerated pharmacologic therapy. Intravenous vasodilators and inotropic agents may also be used in conjunction with temporary MCS to maximize hemodynamic and clinical benefits or to facilitate device removal. Regardless of the modality selected, systemic anticoagulation with intravenous therapies (eg, unfractionated heparin) is required to prevent device thrombosis. Temporary MCS should generally be avoided in patients with irreversible advanced HF and no plan for definitive management, those with contraindications to anticoagulation therapy, and those with comorbid conditions or anatomical abnormalities that preclude device implantation. The three most common modalities of temporary MCS are the IABP, VAD, and extracorporeal membrane oxygenation (ECMO) (Fig. 37-5). Unique features, contraindications, and complications of each type of device will be discussed in the sections to follow.

FIGURE 37-5

Common types of temporary MCS. An intra-aortic balloon pump (IABP) is advanced into the descending aorta where it inflates during diastole (shown), displacing blood and improving coronary filling. During systole (not shown), the IABP deflates, producing a vacuum-like effect that reduces peripheral resistance. An example of a percutaneous VAD is the Impella device, which is advanced through the aortic valve, where blood is transferred from the left ventricle to the aorta by an axial flow pump. The TandemHeart VAD is also a device inserted percutaneously into a large peripheral vein and advanced across the intra-atrial septum. Blood is removed from the left atrium and propelled by an extracorporeal centrifugal flow pump back into the systemic circulation (not shown). The CentriMag VAD uses an inflow cannula that is surgically inserted into the apex of the left ventricle, where blood is transferred to an extracorporeal centrifugal flow pump (not shown), where it is returned to the systemic circulation via an outflow cannula surgically inserted into the aorta. In extracorporeal membrane oxygenation (ECMO) (not shown), the inflow and outflow cannula are inserted into peripheral vessels.

Intra-aortic Balloon Pump

An IABP consists of a polyethylene balloon mounted on a catheter that is inserted percutaneously into the femoral artery and advanced into the descending thoracic aorta (see Fig. 37-5). During counterpulsation, the balloon is synchronized with the electrocardiogram (or alternatively, changes in pressure) so that it inflates during diastole and displaces blood to the proximal aorta, thus increasing diastolic pressure and coronary perfusion. The balloon deflates just prior to the opening of the aortic valve during systole, which causes a sudden "vacuum-like" decrease in aortic pressure, allowing the left ventricle to pump against reduced arterial impedance. Although the IABP is the most commonly employed modality of temporary MCS due to its ease of use, it only provides an estimated 1.0 L/min of CO. As a consequence, the primary benefits of an IABP are enhanced coronary perfusion, increased myocardial oxygen supply, and reduced myocardial oxygen demand. It may be particularly useful for patients with myocardial ischemia complicated by cardiogenic shock, although it has not been shown to improve mortality in this setting.[54] Systemic anticoagulation is generally recommended, although cases of IABP use without anticoagulation have been reported and practices vary across institutions.[55] Complications of the IABP include vascular injury, thrombocytopenia, and renal impairment due to obstruction of the splanchnic circulation by balloon malposition. Use should be avoided in patients with severe peripheral vascular disease or significant aortic regurgitation (e.g., aortic insufficiency).

Ventricular Assist Devices

A VAD provides hemodynamic support by assisting and, in some cases, replacing the pumping functions of the right and/or left ventricles. Compared to an IABP, temporary VADs confer greater hemodynamic improvements but no differences in long-term survival.[56] A left ventricular assist device (LVAD) propels blood from the left ventricle or left atrium to the ascending aorta whereas a right VAD propels blood from the right ventricle or right atrium to the PA. A right VAD may be used alone or in conjunction with an LVAD; this latter configuration is known as a biventricular assist device. All VADs are preload-dependent, meaning that adequate intra-ventricular filling pressure (ie, volume) is required to optimize blood flow. As with the native ventricle in HF, VADs are also afterload-sensitive, meaning that excess peripheral resistance can impair blood flow. Complications of VAD implantation include bleeding, infections, stroke, and risks associated with the specific implantation technique. In addition, the devices can cause thrombosis, renal and hepatic dysfunction, and arrhythmias. Right ventricular failure is a unique complication of LVAD implantation as a result of increased venous return, persistently elevated pulmonary pressures, and changes in right ventricular geometry.

Percutaneous VADs include the Impella series (Abiomed, Danvers, MA) and TandemHeart (CardiacAssist, Pittsburgh, PA). Most Impella devices are inserted percutaneously into a large peripheral artery and advanced in a retrograde fashion across the aortic valve, where blood is advanced from the left ventricle to the ascending aorta via axial flow (see Fig. 37-5). The amount of CO augmented by the Impella device depends on the model used; for example, the Impella 2.5 and 5.0 models supply 2.5 L and 5.0 L/min of flow, respectively. Hemolysis is a common complication of Impella use due to the axial flow facilitated by the device. The TandemHeart device consists of an inflow cannula placed percutaneously into a large peripheral vein and advanced transseptally into the left atrium (see Fig. 37-5). Blood is withdrawn from the left atrium by an extracorporeal pump and propelled via an outflow cannula placed percutaneously into a large artery. Up to 5.0 L/min of flow can be provided by the TandemHeart. Due to its placement across the intra-atrial septum, perforation and shunt formation are potential complications with this device.

The most common surgically implanted temporary VAD is the CentriMag (Thoractec Corp., Pleasanton, CA), which can provide right, left, or biventricular support and up to 10 L/min of CO. The CentriMag device consists of a centrifugal flow extracorporeal pump and surgically placed inflow and outflow cannula supporting the affected ventricle (see Fig. 37-5). Given the surgical technique required for placement of the CentriMag device, tissue injury is its most common complication.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation may be venoarterial or venovenous in nature. In venoarterial ECMO, deoxygenated blood is transported from the venous circulation to an extracorporeal oxygenator and centrifugal flow pump and returned as oxygenated blood to the arterial circulation. In contrast, venovenous ECMO consists of only extracorporeal oxygenation; hemodynamic support is provided by native cardiac function. As a consequence, venoarterial ECMO is more common in the management of refractory ADHF, where up to 8 L/min of cardiac support can be provided. Complications of ECMO include bleeding, infections, and organ dysfunction. Serum drug concentrations can also be significantly impacted as a result of an increased volume of distribution, decreased elimination due to hepatic and/or renal impairment, and sequestration of drugs in the ECMO circuit.

Advanced Therapies

No consensus definition exists for advanced HF or the stage at which patients should be considered for definitive therapies such as durable MCS and heart transplantation. Nonetheless, evaluation for these advanced therapies is commonly initiated during an admission for ADHF, particularly if hospitalization is accompanied by severe symptoms at rest, intolerance of GDMT, decline in organ function, refractory arrhythmias, or an inability to be successfully weaned from inotropic or temporary MCS support. Because of the complexity of care, potential risks, and resource implications of durable MCS and heart transplantation, patients with advanced HF must undergo a rigorous interdisciplinary evaluation before becoming eligible candidates. Components of this evaluation commonly include past medical, surgical, and psychosocial history, medication and adverse event history, adherence to medications and medical care, comorbid conditions, risks for postoperative complications, and health insurance coverage. Relative contraindications to the use of advanced therapies include excess perioperative risk, irreversible pulmonary hypertension, inability to manage postoperative care (eg, medication therapy, monitoring), and concurrent survival-limiting diseases (eg, malignancy).

Durable MCS

The most common indications for durable MCS are temporary device implantation in patients awaiting heart transplantation who are unlikely to survive the duration of time required for identifying a suitable donor ("bridge to transplantation") and permanent device implantation in patients who are ineligible for heart transplantation due to advanced age or comorbid conditions ("destination therapy"). Although far less common than with temporary MCS, durable VADs may be implanted in patients who are likely to become eligible transplant candidates ("bridge to decision") but the evaluation is incomplete or has been delayed until certain requirements can be satisfied (eg, smoking cessation). Durable MCS is almost exclusively comprised of LVAD implantation, although select patients may remain hospitalized with right VAD or biventricular support while awaiting transplantation.

Durable LVADs are implanted by inserting an inflow cannula into the apex of the left ventricle, which is connected to an intracorporeal pumping unit; blood is returned to the systemic circulation via an outflow cannula inserted into the aorta. Whereas previous devices provided hemodynamic support via pulsatile flow, newer-generation devices utilize a continuous flow mechanism, allowing them to be smaller in size, less subject to deterioration over time, and conferring an improvement in event-free survival.[57] Prolonged unloading of the left ventricle with an LVAD in combination with drug therapy can produce sustained recovery in LV function, amelioration of symptoms, and in some cases, device explantation.[58] The three continuous flow LVADs currently approved for use in the United States are the axial flow HeartMate II LVAD (Abbott; Lake Bluff, IL) and centrifugal flow HeartMate 3 LVAD (Abbott) and HeartWare Ventricular Assist Device (HVAD) (HeartWare, Inc; Framingham, MA). All three devices are capable of providing up to 10 L/min of CO. For complete heart replacement therapy, total artificial heart systems continue to be investigated, although their size and embolic complications limit widespread use.

Complications following durable LVAD placement are similar to those described for temporary devices. Device malfunction may occur with long-term use but has become rare with advances in technology. The most perplexing challenge in the care of LVAD patients remains identifying a chronic antithrombotic regimen that balances the risk of device thrombosis and bleeding. Antithrombotic regimens most often include a vitamin K antagonist and antiplatelet agent, although the goal international normalized ratio (INR) range and antiplatelet agents selected (eg, aspirin, dipyridamole, clopidogrel) may vary significantly by the center. The efficacy and safety of direct oral anticoagulants in LVAD recipients have yet to be established. Suspected pump thrombosis should be promptly evaluated, although no consensus exists on an appropriate treatment strategy (eg, enhanced antiplatelet or anticoagulant therapy, thrombolysis, or pump exchange).[59]

Heart Transplantation

⑫ Orthotopic heart transplantation remains the optimal management strategy for patients with irreversible advanced HF, as 10-year survival rates approach 60% among patients transplanted after 2001.[60] Unfortunately, the shortage of acceptable donor hearts has prolonged waiting times and many patients succumb to their disease prior to transplantation. Another significant percentage of patients are deemed ineligible for heart transplantation because of age, concurrent illnesses, psychosocial factors, or other reasons. The shortage of donor hearts has prompted the development of new surgical strategies, including ventricular aneurysm resection, mitral valve repair, and myocardial cell transplantation, which have resulted in variable degrees of improvement. Further development of these and other techniques may offer additional options in patients who are not eligible for VAD implantation or heart transplantation. For a more detailed discussion of heart transplantation, see Chapter 109 "Solid Organ Transplantation."

EVALUATION OF THERAPEUTIC OUTCOMES

Daily monitoring to assess the efficacy of drug therapy is critical to assuring optimal outcomes and should include weight, strict measurement of fluid intake and output, and HF signs and symptoms (Table 37-6). Foley catheter placement is not recommended unless close monitoring of urine output is not otherwise possible. Safety endpoints such as monitoring for electrolyte depletion, symptomatic hypotension, and renal dysfunction should be assessed frequently. While many safety parameters can be monitored daily, some will need to be monitored more frequently based on the patient's clinical status. Vital signs should be assessed multiple times throughout the day at a frequency that is appropriate for the patient's degree of stability. Orthostatic blood pressure should be assessed at least once daily.

TABLE 37-6

Monitoring Recommendations for Patients Hospitalized with ADHF

Parameter	Frequency	Notes
Weight	Daily	Assess after voiding in the morning
		Use the same scale each day, standing weight if possible
		Account for increase or decrease in food intake
Fluid balance	Daily[a]	Strict intake and output
Vital signs	More than daily	Blood pressure and heart rate, including signs/symptoms of orthostatic hypotension, rhythm (continuous)
Signs of congestion and/or low output	Daily[a]	Jugular venous distension, crackles, hepatomegaly, splenomegaly, hepatojugular reflux, ascites, lower extremity edema, hypotension, narrow pulse pressures, cool extremities, altered mental status, worsening renal or hepatic function
Symptoms of congestion and/or low output	Daily[a]	Dyspnea on exertion or at rest, orthopnea, paroxysmal nocturnal dyspnea, nausea/vomiting, early satiety, fatigue, lightheadedness, chest pain, palpitations
Electrolytes	Daily[a]	Potassium, magnesium, sodium
Renal function	Daily[a]	Blood urea nitrogen and serum creatinine including ratio to assess volume status (ie, over-diuresis)
Hepatic function	Variable[a]	Alk Phos and GGT primarily for fluid overload, AST and ALT primarily for hypoperfusion
BNP, NT-proBNP	Admission, discharge	Admission for diagnosis, discharge for prognosis
Other	Variable	Troponin and other cardiac enzymes if myocardial strain
		Arterial blood gas if hypoxic
		Lactate, if hypoperfusion present
		Iron panel, regardless of hemoglobin concentrations

Alk Phos, alkaline phosphatase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; BNP, B-type natriuretic peptide; GGT, gamma-glutamyltransferase; NT-proBNP, N-terminal pro-B-type natriuretic peptide.

[a] Daily unless a change in clinical status warrants more frequent assessment (eg, high-dose, continuous infusion, and/or combination diuretic therapy; rapidly changing clinical status).

Patients with ADHF may have critically reduced CO, usually with low arterial blood pressure and systemic hypoperfusion resulting in organ system dysfunction (ie, cardiogenic shock). They may also have pulmonary edema with hypoxemia, respiratory acidosis, and markedly increased work of breathing. With cardiopulmonary support, response to interventions should be assessed promptly to allow for timely adjustments in treatment. Continuous telemetry monitoring, continuous pulse oximetry, urine flow, and automated blood pressure recordings are standards of care for critically ill patients with cardiopulmonary decompensation. Peripheral or femoral arterial catheters may be used for continuous and accurate assessment of arterial pressure.

Preparing for Discharge

Patients should not be discharged until optimal volume status is achieved and they have been successfully transitioned from an IV to an oral diuretic regimen and IV inotropes and vasodilators have been discontinued for at least 24 hours. Given the known benefits of discharging patients on GDMT, hospitalization for ADHF represents an ideal opportunity to optimize these therapies. As such, efforts should be made to initiate (or reinitiate if held earlier in the admission) GDMT in hemodynamically stable patients without contraindications.[3] For example, low-dose β-blocker therapy may be safely initiated at discharge without increasing the risk of readmission,[61] and transitioning eligible patients to the angiotensin receptor neprilysin inhibitor (ARNI) sacubitril/valsartan should also be considered.[62] Patients who are hemodynamically stable and have been successfully transitioned to oral diuretics should be considered for SGTL2 inhibitor therapy given reductions in the risk of cardiovascular death and rehospitalization when these therapies are initiated prior to or shortly after discharge.[63] In patients with iron deficiency (ie, serum ferritin <100 ng/mL (mcg/L) or 100 to 299 ng/mL (mcg/L) with transferrin saturation <20%), IV iron repletion should be considered prior to or shortly after discharge to improve symptoms and quality of life and potentially reduce the risk of HF rehospitalization.[64] If relevant, smoking cessation must be addressed to avoid delay in consideration for advanced therapies. In patients with reduced LVEF, use of GDMT or intolerance to such should be documented in the medical record.[65]

Prior to discharge, patients and caregivers should be counseled on dietary sodium restriction as well as monitoring body weight daily and parameters for when to titrate diuretics or call a healthcare provider for further instruction (eg, 3-lb (1.4 kg) weight gain in 24 hours). Medication changes (initiation, discontinuation, dose change) should be clearly conveyed verbally and in writing and financial coverage for all medication assured. The importance of dietary and medication adherence should be emphasized. Appropriate follow-up should be scheduled, including an appointment within 7 days post-discharge and a nurse visit or phone call at 3 days for select patients. Pertinent follow-up labs (eg, potassium, serum creatinine) should also be scheduled, including other medication-related labs (eg, INR for warfarin, serum digoxin concentration). All patients should be considered for referral to a multidisciplinary disease management program.[66,67]

CONCLUSION

Several recent clinical trials have addressed many controversies in the management of ADHF, including the appropriate dosing of diuretics and the use of vasoactive therapies in patients with volume overload. Still, many unanswered questions remain, including optimal use of GDMT in the setting of ADHF. Many advances in MCS have extended the lives of patients awaiting a transplant; however, limited evidence exists to guide the management of this patient population, including how to avoid and manage complications associated with these devices. Finally, ideal management of patients with ADHF includes optimization of GDMT, optimal communication with patients, caregivers, and other healthcare providers with each care transition, and outpatient follow-up with a collaborative, multidisciplinary team.

SELF-ASSESSMENT QUESTIONS

A 58-year-old male with a history of ischemic cardiomyopathy presents to clinic with orthopnea, dyspnea with minimal exertion, 3+ pitting edema, fatigue, anorexia, nausea, and early satiety.

1. These signs and symptoms are consistent with:
   - A. Volume overload only
   - B. Low cardiac output only
   - C. Both volume overload and low cardiac output
   - D. Neither volume overload or low cardiac output
2. A 62-year-old female is admitted to the hospital with acute decompensated heart failure and a pulmonary artery catheter is placed. The pulmonary capillary wedge pressure is 28 mm Hg and the cardiac index is 1.8 L/min/m^2 (0.03 L/s/m^2). These hemodynamic values are consistent with which one of the following hemodynamic subsets?
   - A. I (warm and dry)
   - B. II (warm and wet)
   - C. III (cold and dry)
   - D. IV (cold and wet)
3. All of the following strategies would be reasonable for overcoming diuretic resistance in a patient currently receiving furosemide 120 mg IV twice daily, *EXCEPT*:
   - A. Adding spironolactone 25 mg orally once daily
   - B. Increasing the dose of furosemide to 240 mg IV twice daily
   - C. Increasing the frequency of furosemide to 120 mg IV three times daily
   - D. Adding metolazone 2.5 mg orally once daily
4. Which of the following laboratory values should be monitored to assess the safety of furosemide? Select all that apply.
   - A. Brain natriuretic peptide
   - B. Serum creatinine
   - C. Potassium
   - D. Liver transaminases
5. A patient is admitted with acute decompensated heart failure and evidence of low cardiac output. The patient's current medications include sacubitril/valsartan 49/51 mg twice daily, furosemide 40 mg twice daily, metoprolol succinate (CR/XL) 200 mg daily, and digoxin 0.125 mg daily. The patient has been stable on these doses for the previous 4 months. The team decides that inotropic therapy is indicated. Which of the following would be an appropriate agent to initiate at this time?
   - A. Dopamine
   - B. Dobutamine
   - C. Milrinone

D. Either B or C

Questions 6 through 8 refer to the following case:

A 57-year-old African American patient with ischemic cardiomyopathy (ejection fraction 25% [0.25]) presents to the emergency department (ED) with acute decompensated heart failure. His vital signs include blood pressure 103/77 mm Hg (negative for orthostasis), heart rate 92 bpm, respiratory rate 23 rpm, and oxygen saturation 91% [0.91] on 4 L by nasal cannula. Physical examination reveals jugular venous distension, crackles at the bases bilaterally, ascites, and trace bilateral lower extremity edema. The patient reports to a 10 lb (4.5 kg) weight gain in the past 2 weeks since his metoprolol dose was increased despite strict adherence to both dietary restrictions and medications. In the ED, he already received furosemide 160 mg IV once with minimal response in urine output. Pertinent labs include potassium 5.1 mEq/L (mmol/L), B-type natriuretic peptide 950 pg/mL (ng/L; 275 pmol/L), blood urea nitrogen 32 mg/dL (11.4 mmol/L), and serum creatinine 2.2 mg/dL (194 µmol/L) (baseline). The patient's medications on admission include lisinopril 10 mg daily, metoprolol succinate (CR/XL) 150 mg daily, and furosemide 120 mg twice daily.

6. How should the patient's β-blocker be managed at this time?

   A. Continue at the current dose

   B. Discontinue immediately

   C. Reduce to the last tolerated dose

   D. Change to atenolol

7. Which of the following would be appropriate for managing this patient's volume overload?

   A. Initiate furosemide 160 mg IV twice daily

   B. Change to bumetanide mg IV twice daily

   C. Initiate furosemide 20 mg/h IV continuous infusion plus metolazone 5 mg by mouth daily

   D. Initiate furosemide 5 mg/h IV continuous infusion

8. Which of the following guideline-directed medical therapies would be appropriate to initiate prior to this patient's discharge? (Assume discharge laboratory values are identical to the admission values provided above.)

   A. Spironolactone 25 mg by mouth once daily

   B. Digoxin 0.125 mg by mouth once daily

   C. Candesartan 4 mg by mouth once daily

   D. Isosorbide dinitrate 20 mg and hydralazine 37.5 mg by mouth three times daily

Questions 9 through 11 refer to the following case:

A 63-year-old female with hypertensive cardiomyopathy (ejection fraction 30%–35% [0.30-0.35]) presents with a chief complaint of "always feeling tired." Her daughter reports that the patient's exercise tolerance has significantly declined recently despite strict adherence to a low-sodium diet and medications that include sacubitril/valsartan 24/26 mg twice daily, carvedilol 12.5 mg twice daily, furosemide 80 mg twice daily, and digoxin 0.125 mg daily. Vital signs include blood pressure 92/57 mm Hg (mild orthostasis), heart rate 95 bpm, and respiratory rate 16 rpm. On physical examination, she has no findings consistent with volume overload. Laboratory analysis reveals sodium 135 mEq/L (mmol/L), potassium 4.9 mEq/L (mmol/L), blood urea nitrogen (BUN) 45 mg/dL (16.1 mmol/L), and serum creatinine (SCr) 2.2 mg/dL (194 µmol/L) (baseline BUN 27 mg/dL [9.6 mmol/L] / SCr 1.1 mg/dL [97 µmol/L]). Upon further questioning, the patient admits to occasional dizziness.

9. In which of the following hemodynamic subsets should this patient be placed?

A. Subset I (warm and dry)

B. Subset II (warm and wet)

C. Subset III (cold and dry)

D. Subset IV (cold and wet)

10. Which of the following laboratory parameters would assist in confirming the volume status of this patient?

A. C-reactive protein

B. B-type natriuretic peptide

C. Serum albumin

D. Hemoglobin

11. Which of the following would be the optimal initial intervention for this patient?

A. Change furosemide to 80 mg IV twice daily

B. Hold furosemide and initiate cautious hydration with IV fluids

C. Hold carvedilol and initiate dobutamine at 2 mcg/kg/min IV

D. Increase carvedilol to 25 mg by mouth twice daily

12. Compared to dobutamine, which of the following is true regarding milrinone?

A. Lower risk of hypotension

B. Greater dependence on hepatic clearance

C. Longer elimination half-life

D. Increased risk of arrhythmias

Questions 13 and 14 refer to the following case:

An 84-year-old white male with ischemic cardiomyopathy (ejection fraction 20%-25% [0.20-0.25]) presents to the hospital with acute decompensated heart failure. Vital signs include blood pressure 89/55 mm Hg, heart rate 93 bpm (no orthostasis present), and respiratory rate 20 rpm. Physical examination reveals jugular venous distention, positive S3 sound, bilateral crackles throughout on lung auscultation, and 3+ bilateral edema to the thighs. Chest radiograph reveals pulmonary edema and pleural effusions. Hemodynamic measurements obtained by pulmonary artery catheter include pulmonary capillary wedge pressure 28 mm Hg, cardiac index 1.7 L/min/m^2 (0.028 L/s/m^2), and systemic vascular resistance 1,000 dyne·s·cm^{-5} (12.5 Wood units; 100 MPa·s/m^3). The patient's laboratory values are all normal, except blood urea nitrogen (BUN) 34 mg/dL (12.1 mmol/L), and serum creatinine (SCr) 1.5 mg/dL (133 µmol/L) (baseline BUN 32 mg/dL [11.4 mmol/L] and 0.9 mg/dL [80 µmol/L]). Medications on admission include lisinopril 10 mg daily, bisoprolol 10 mg daily, bumetanide 2 mg twice daily, atorvastatin 40 mg daily, and aspirin 81 mg daily.

13. Which of the following would be an appropriate initial strategy for managing this patient's volume overload?

A. Furosemide 80 mg IV twice daily

B. Furosemide 80 mg IV twice daily plus metolazone 10 mg by mouth once daily

C. Furosemide 20 mg/h IV continuous infusion

D. Nitroglycerin 25 mcg/min IV continuous infusion

14. Which of the following therapies would be appropriate for managing this patient's low output?

    A. Sodium nitroprusside 0.1 mcg/kg/min IV continuous infusion

    B. Nitroglycerin 25 mcg/min IV continuous infusion

    C. Dopamine 10 mcg/kg/min IV continuous infusion

    D. Dobutamine 2 mcg/kg/min IV continuous infusion

15. Which of the following modalities of temporary mechanical circulatory support provides the least amount of hemodynamic support?

    A. Intra-aortic Balloon Pump

    B. Percutaneous VAD (eg, Impella Device)

    C. Surgical VAD (eg, Centrimag)

    D. Extracorporal Membrane Oxygenation (ECMO)

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The patient is exhibiting signs and symptoms of volume overload (orthopnea, dyspnea, nausea, 3+ pitting edema). In addition, the patient is exhibiting symptoms of low cardiac output (fatigue, early satiety). Early satiety may be a symptom of either volume overload due to fluid accumulation around the stomach (ie, abdominal edema) or low cardiac output due to reduced blood flow to the stomach. (See Clinical Presentation; Table 37-1)

2. **D.** The patient's elevated PCWP of 28 mm Hg indicates volume overload (wet) and the decreased cardiac index of 1.8 L/min/m^2 (0.03 L/s/m^2) indicates low cardiac output (cold). Consequently, the patient would fall into subset IV of cold and wet (making all of the remaining combinations incorrect). (See Invasive Hemodynamic Monitoring; Fig. 37-1)

3. **A.** At a dose of 25 mg daily, spironolactone produces only minimal diuretic effects and would be unlikely to overcome diuretic resistance, even when combined with a loop diuretic. Lower doses of spironolactone inhibit myocardial fibrosis and pathologic remodeling in chronic heart failure, but much higher doses are required to reliably augment diuresis. Increasing the dose of furosemide will shift drug concentrations toward the top of the concentration-response curve and improve diuresis, so answer choice B is incorrect. Changing to furosemide 120 mg IV three times daily would increase the daily dose and may be effective if the patient is making urine in response to 120 mg but is not achieving overall diuresis goals, so answer choice C is incorrect. Adding metolazone, a thiazide-type diuretic, would produce a synergistic diuretic effect due to sequential nephron blockade, so answer choice D is incorrect. (See Strategies to Overcome Diuretic Resistance)

4. **B** and **C**. Furosemide and other loop diuretics can cause acute kidney injury when diuresis is too rapid, which is why serum creatinine should be routinely monitored (Answer B). Additionally, loop diuretics can cause several electrolyte abnormalities, with hypokalemia and hypomagnesemia being the perturbations observed most frequently (Answer C). Elevations in brain natriuretic peptide reflect stretch-mediated injury in the myocardium (ie, due to excess volume) and would not indicate furosemide toxicity, making answer choice A incorrect. Finally, liver transaminases such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST) can be a reflection of low cardiac output (ie, cardiogenic shock), but they are not used to monitor the safety of furosemide, making answer choice D incorrect. (See Loop Diuretics; Table 37-5)

5. **D.** Either dobutamine or milrinone would be a reasonable option for this patient, as both agents have been shown to produce similar hemodynamic effects in patients receiving metoprolol (making answer choices B and C incorrect). Traditionally, milrinone has been advocated in patients receiving chronic β-blocker therapy because its inotropic effects do not involve β-receptor stimulation. However, research has shown that the hemodynamic effects of dobutamine may persist in the presence of chronic β-blocker therapy, particularly with β_1-selective agents. Since the patient is not presenting in a mixed shock state (eg, cardiogenic and vasodilatory shock), dopamine would not be an appropriate choice (answer A), given its variable inotropic and vasopressor effects. (See Inotropes, Inotrope Selection)

6. **C.** The patient's metoprolol dose was recently increased and may be responsible for his acute decompensation due to its negative inotropic effects. As such, the dose of metoprolol should be reduced back down to the patient's last tolerated dose. Metoprolol should not be discontinued in the absence of evidence of low output as stopping a patient's β-blocker during an acute decompensation has been associated with worse outcomes, making answer choice B incorrect. Changing metoprolol to atenolol would not be helpful as atenolol has not been shown to improve outcomes in heart failure, making answer choice D incorrect. Continuing the current dose (answer A) would only be warranted if the dose had been stable for a reasonable period (ie, several weeks) prior to the acute decompensation. (See General Approach to Treatment)

7. **C.** Initiating a furosemide regimen at up to 2.5 times the patient's home dose (a 20 mg/h infusion would be 480 mg/day or twice that of her home regimen), plus adding metolazone, a thiazide-type diuretic with an alternative mechanism of action, would produce a synergistic diuretic effect due to sequential nephron blockade. Since the patient had a minimal response to furosemide 160 mg IV, it is unlikely that the threshold for diuresis has been reached; scheduling this dose more frequently would therefore be unlikely to elicit a diuretic response, making answer choice A incorrect. Changing to bumetanide 2 mg IV twice daily would represent a decrease from the dose she received in the ED (as the equipotency of IV bumetanide to IV furosemide is approximately 1 to 20-40), making answer choice B incorrect. Administering a continuous infusion of furosemide at 5 mg/h would also be an overall dose decrease (ie, an equivalent of furosemide 120 mg IV over a 24-hour period), so answer choice D is incorrect. (See Loop Diuretics; Strategies to Overcome Diuretic Resistance)

8. **D.** In self-identified African American patients with New York Heart Association class III-IV symptoms, the combination of isosorbide dinitrate and hydralazine has been shown to reduce mortality and hospitalizations when added to a background of ACE inhibitor and β-blocker therapy. Answer choice A would be incorrect since the patient's potassium is 5.1 mEq/L (mmol/L) and adding spironolactone would likely exacerbate hyperkalemia, especially given baseline renal dysfunction. Whereasdigoxin may improve the patient's symptoms and reduce the risk of rehospitalization, it is usually reserved for patients with advanced disease who have already been optimized on therapies associated with improvements in survival. Notably, renal dysfunction would not be a contraindication to digoxin as long as serum concentrations could be maintained within the appropriate range. Answer choice C is incorrect since the patient is already on lisinopril and candesartan would likely worsen the patient's renal function and hyperkalemia. (See Preparing for Discharge)

9. **C.** The patient does not have any signs of fluid overload as evidenced by physical exam, making answer choices B and D incorrect. Instead, she presents with signs and symptoms of both hypoperfusion (answer A is incorrect) and being volume-depleted—complaining of fatigue, having a blood pressure of 92/57 mmHg with mild orthostasis and an elevated BUN and SCr, and endorsing occasional dizziness. (See Clinical Presentation; Table 37-1)

10. **B.** B-type natriuretic peptide (BNP) is a counterregulatory neurohormone released in response to increased filling pressures. A BNP concentration that is not increased from baseline would have a strong negative predictive value for ruling out the presence of volume overload. C-reactive protein is a marker of inflammation and would not be helpful for confirming the patient's volume status, so answer choice A is incorrect. Serum albumin is primarily a marker of nutritional status, so answer choice C is incorrect. Hemoglobin is primarily a marker of anemia, so answer choice D is incorrect. (See Laboratory Findings)

11. **B.** Since the patient is volume depleted, her furosemide should be held and cautious hydration with IV fluids should be administered. Changing furosemide to 80 mg IV twice daily would further worsen dehydration and kidney dysfunction, so answer choice B is incorrect. Although the patient has evidence of hypoperfusion, this is likely due to lack of volume (ie, low end of the Frank–Starling curve) and inotropic support should not be considered until a euvolemic state has been achieved. Hence, holding carvedilol and initiating dobutamine would not be appropriate at this time, making answer choice C incorrect. Answer choice D is incorrect, given the potential negative inotropic effects associated with higher β-blocker doses; carvedilol should be maintained at its current dose until evidence of hypoperfusion has resolved. (See General Approach to Treatment; Loop Diuretics; Fig. 37-1)

12. **C**. Although outcomes between dobutamine and milrinone are generally similar in patients with cardiogenic shock, some pharmacologic differences may make one of the two therapies more optimal in a given patient. One of the disadvantages of milrinone is its longer elimination half-life compared to dobutamine (Answer C), which prevents minute-to-minute titrations in hemodynamically labile patients. Answer choice A is incorrect because milrinone has a higher, not lower, risk of hypotension due to its vasodilating effects in vascular smooth muscle. Answer choice B is incorrect because milrinone is primarily dependent on renal rather than hepatic clearance. Finally, the risk of arrhythmias is similar between dobutamine and milrinone, making answer choice D incorrect. (See Inotropes)

13. **A.** The patient is presenting with volume overload requiring aggressive diuresis. Furosemide 80 mg IV twice daily would be a reasonable initial dose

given the patient's low blood pressure and acutely elevated serum creatinine. Notably, if these signs of hypoperfusion were not present, a more aggressive dose (eg, up to 2.5 times the oral home dose administered intravenously) would be appropriate, as high doses have been associated with more rapid relief of congestive symptoms. Combination diuretic therapy (ie, addition of a thiazide-type diuretic such as metolazone) may be considered in patients with refractory congestive symptoms, but this approach is usually reserved for patients who have failed an adequate trial of loop diuretics, making answer choice B incorrect. Answer choice C is incorrect since a continuous infusion of furosemide at 20 mg/h would be equivalent to furosemide 480 mg IV over a 24-hour period and would exceed the initial dose increases shown to be safe in patients with acute decompensated heart failure. Vasodilators may be considered for the treatment of refractory congestive symptoms, but such therapy should be avoided in patients with hypotension, making answer choice D incorrect. (See Loop Diuretics; Strategies to Overcome Diuretic Resistance)

14. **D.** Since the patient's cardiac index is low and systemic vascular resistance is normal, positive inotropic therapy should be considered. Answer choices B, C, and D are incorrect since these medications are strictly vasodilators and are contraindicated in patients with low blood pressure in the absence of elevated systemic vascular resistance. Finally, answer choice C would be incorrect because dopamine exerts unpredictable effects and its inotropic action at 10 mcg/kg/min would be accompanied by vasoconstriction, which may further worsen left ventricular dysfunction. (See General Approach to Treatment; Vasodilators; Inotropes; Fig. 37-1).

15. **A**. Despite its frequent use, intra-aortic balloon pump counterpulsation provides the least amount of hemodynamic support (approximately 1 L/min of cardiac output) among the options listed. The remaining modalities all provide considerably greater levels of hemodynamic support, with augmentation in cardiac output ranging from 2.5 with select percutaneous ventricular assist devices (eg, Impella 2.5) to 10 L/min with surgical ventricular assist devices (eg, CentriMag). (See Temporary Mechanical Circulatory Support)

Chapter 38: Venous Thromboembolism

Daniel M. Witt; Nathan P. Clark; Sara R. Vazquez

KEY CONCEPTS

KEY CONCEPTS

① Venous thromboembolism (VTE) is often associated with identifiable risk factors.

② The diagnosis of suspected VTE should be confirmed by objective testing.

③ During hospitalization, patients should receive VTE prophylaxis based on the VTE risk factors present and the anticipated duration of risk.

④ Initial VTE treatment should include a rapid-acting anticoagulant.

⑤ For VTE treatment, injectable anticoagulants should be overlapped with warfarin for at least 5 days and until the patient's international normalized ratio is ≥2.0 for at least 24 hours.

⑥ Direct oral anticoagulants (DOACs) such as apixaban, dabigatran, edoxaban, and rivaroxaban are significant advancements in VTE prevention and treatment.

⑦ Most patients with uncomplicated deep vein thrombosis (DVT) or pulmonary embolism (PE) can be safely treated as outpatients.

⑧ Most patients with VTE should receive 3 months of anticoagulation therapy; treatment beyond 3 months should be based on the risk of VTE recurrence and bleeding as well as patient preferences.

⑨ Optimal anticoagulant therapy management requires knowledge of pharmacologic and pharmacokinetic characteristics as well as a systematic management approach with ongoing patient education.

BEYOND THE BOOK

BEYOND THE BOOK

Visit the **National Blood Clot Alliance: Stop The Clot** website and read the stories of at least five different patients (https://www.stoptheclot.org/patient-stories/). These stories are useful to enhance student understanding regarding the impact of VTE and its treatment on the lives of patients and their families.

INTRODUCTION

Venous thromboembolism (VTE) is a potentially fatal disorder and a significant health problem in our aging society.[1] VTE results from clot formation within the venous circulation and manifests as deep vein thrombosis (DVT) and/or pulmonary embolism (PE) (Fig. 38-1).[1] DVT is rarely fatal, but PE can result in death within minutes of symptom onset before effective treatment can be given. Late VTE complications, such as the postthrombotic syndrome and chronic thromboembolic pulmonary hypertension (CTPH), also cause substantial morbidity.[1] Identifying VTE risk factors is important for targeting patients at high risk for VTE who would most benefit from VTE prevention strategies.[2,3]

Rapid and accurate diagnosis is critical to making appropriate treatment decisions when VTE is suspected.[4] Optimal prevention and treatment of VTE using anticoagulant drugs requires an in-depth knowledge of their pharmacology and pharmacokinetic properties, and a comprehensive approach to patient management.[5] Bleeding is a common and serious complication of anticoagulant therapy.[5]

EPIDEMIOLOGY

VTE is associated with a significant global disease burden.[6] The incidence rate of symptomatic first VTE is estimated at 132 per 100,000 patient-years and occurs more frequently in women (55.6%).[7] When standardized by age, Asian patients appear to have the lowest VTE incidence (122 per 100,000 patient-years) followed by White (191) and Black (203) patients.[7] Recurrent VTE rates are highest in the 180 days following the initial event and decline slowly over the next 4 to 10 years. In the absence of secondary prevention, the 10-year cumulative recurrent VTE risk is approximately 25.0%.[7]

ETIOLOGY

① A number of identifiable factors increase VTE risk (Table 38-1). Many risk factors fall into categories constituting what is known as Virchow's triad: blood stasis, vascular injury, and hypercoagulability.

TABLE 38-1

Risk Factors for VTE

Risk Factor	Comments/Examples
Age	Incidence of VTE in adults age 75 and older is seven to ten times higher than adults younger than 55 years, with risk increasing even more over age 85
Prior VTE History	Potent risk factor for recurrence; risk is highest during the first 180 days after VTE
Blood stasis	• Acute medical illness requiring hospitalization • Surgery (especially general anesthesia >30 minutes) • Paralysis (eg, status post-stroke, spinal cord injury) • Immobility (eg, plaster casts, status post-stroke, or spinal cord injury) • Polycythemia vera • Obesity
Vascular injury	• Major orthopedic surgery (eg, knee or hip replacement) • Trauma (especially fractures of the pelvis, hip, or leg) • Indwelling venous catheters
Hypercoagulability	• Malignancy • Factor V Leiden (homozygous >>heterozygous) • Prothrombin (G20210A) gene mutation • Protein C deficiency • Protein S deficiency • Antithrombin deficiency • Factor VIII excess (>90th percentile) • Factor XI excess (>90th percentile) • Antiphospholipid antibodies ○ Lupus anticoagulant ○ Anticardiolipin antibodies (IgG and/or IgM >99th percentile) ○ Anti–β_2-glycoprotein I antibodies (IgG and/or IgM >99th percentile) • Inflammatory bowel disease • Nephrotic syndrome • Paroxysmal nocturnal hemoglobinuria • Pregnancy or up to 6 weeks postpartum • Drug therapy (eg, estrogen-containing contraceptives, estrogen replacement therapy, tamoxifen, raloxifene, cancer therapy, heparin-induced thrombocytopenia)

Data from References 2,3, 8-10.

Blood Stasis

Blood stasis favors clotting in part through concentrating the elements responsible for blood clot formation.[11] Contraction of the calf and thigh muscles coupled with one-way valves in leg veins facilitate blood flow back to the heart and lungs. Thus, damage to venous valves and prolonged immobility result in venous stasis, which partly explains why numerous medical conditions and surgical procedures are associated with increased VTE risk (Table 38-1).[12]

Vascular Injury

An intact vascular endothelium separates flowing blood from subendothelial vessel wall components responsible for preventing blood loss through clot formation (see detailed description in section "Pathophysiology"). Vascular injury (eg, surgery, trauma) disrupts this protective barrier initiating blood clot formation.[13]

Hypercoagulability

Several inherited and acquired disorders as well as drugs have been linked to blood hypercoagulability (Table 38-1). Estrogen-containing contraception, estrogen replacement therapy, and selective estrogen receptor modulators are all linked to VTE risk.[8] Women with inherited hypercoagulability disorders are at particularly high risk of developing VTE during pregnancy and while taking estrogen.[8]

In many cases, VTE results from combinations of inherited and acquired thrombotic risk factors. Thus, an individual with inherited hypercoagulability may experience VTE only after being placed in high-risk situations such as surgery, immobilization, the use of estrogen-containing oral contraceptives, or pregnancy. Approximately a third of VTEs are provoked by identifiable risk factors.[7]

PATHOPHYSIOLOGY

Hemostasis is the process responsible for maintaining circulatory system integrity following blood vessel damage (Fig. 38-2).[13] Hemostatic clots are formed rapidly and remain localized to the vessel wall without significantly impairing blood flow. In contrast, pathologic clots like those causing VTE form slowly, impair blood flow, and often cause complete vessel occlusion.[13]

Collagen and tissue factor (TF) form a subendothelial hemostatic barrier around blood vessels and organs. Under normal circumstances, endothelial cells lining the vessel wall physically separate collagen and TF from circulating platelets and clotting factors (namely, activated factor VII [VIIa]). Vessel injury results in platelet activation and TF-mediated clotting factor cascade initiation that culminates in thrombin formation. Ultimately, a fibrin clot forms and seals the breach (Fig. 38-2).[13] In contrast to physiologic hemostasis, pathologic VTE often occurs without gross vessel wall damage and may be triggered by TF brought to the growing thrombus by circulating microparticles. Venous clots are mainly composed of fibrin, platelets, and trapped red blood cells and often occur in areas of disturbed blood flow, like deep leg vein valve cusps.[13]

Platelet and coagulation cascade activation occur nearly simultaneously. Platelets become actively involved in thrombus formation after binding to adhesion proteins like von Willebrand factor and collagen when blood is exposed to damaged vessel endothelium.[13] A platelet thrombus grows as activated platelets recruit and activate additional platelets. Activated platelets change shape and release components critical for sustaining further thrombus formation into the environment surrounding the developing clot.[13] Activated platelets accumulating in the thrombus also express P-selectin, an adhesion molecule that facilitates the capture of blood-borne TF bearing microparticles resulting in fibrin clot formation via the coagulation cascade (Fig. 38-3).[13] Activated platelets provide phospholipid-rich surfaces necessary for coagulation cascade reactions.[13]

FIGURE 38-3

Model of pathologic thrombus formation: (A) activated platelets adhere to vascular endothelium; (B) activated platelets express P-selectin; (C) pathologic microparticles express active tissue factor and are present at a high concentration in the circulation—these microparticles accumulate, perhaps by binding to activated platelets expressing P-selectin; (D) tissue factor can lead to thrombin and fibrin generation. The conceptual coagulation cascade model has evolved from the classic depiction of extrinsic, intrinsic, and common pathways (Fig. 38-4) to one in which highly regulated reactions take place on cell surfaces in three overlapping phases: initiation, amplification, and propagation. The cascade starts on TF-bearing cells and continues on the surfaces of activated platelets (Fig. 38-5).[13]

The initiation phase takes place on TF-bearing cells exposed after vessel injury or captured via P-selectin (Fig. 38-3). The TF/VIIa complex (known as extrinsic tenase) activates limited amounts of factors IX and X. Factor Xa then associates with factor Va to form the prothrombinase complex, which cleaves prothrombin (factor II) to generate a small (picomolar) amount of thrombin (factor IIa) which activates factors V, VIII, and XI on platelet surfaces (Fig. 38-5). Factor IXa moves from TF-bearing cells to the surface of activated platelets in the growing platelet thrombus. Tissue factor pathway inhibitor

(TFPI), an important regulator of TF/FVIIa-induced coagulation, rapidly terminates the initiation phase.[13]

The propagation phase is characterized by a burst of thrombin generation as VIIIa/IXa (known as "intrinsic tenase") promotes factor Xa formation and prothrombinase complexes assemble on the surface of activated platelets accelerating thrombin generation. Thrombin generation is further supported by factor XIa bound to the platelet surface, which activates factor IX to form an additional intrinsic tenase.[13]

Thrombin generated during the propagation phase converts fibrinogen to fibrin monomers that precipitate and polymerize to form fibrin strands. Factor XIIIa, which is also activated by thrombin, covalently bonds these strands together (Fig. 38-5) to form an extensive meshwork that surrounds and encases the aggregating platelet thrombus and red blood cells to form a stabilized fibrin clot.[13] Clot formation eventually terminates when the expanding meshwork of platelets and fibrin "paves over" the initiation site preventing activated factors from diffusing through the overlying clot layer.

A number of tempering mechanisms control coagulation (Fig. 38-2). Without effective self-regulation, thrombus formation results in vascular occlusion. Intact endothelium adjacent to the growing thrombus actively produces several antithrombotic substances.[11] Thrombomodulin modulates thrombin activity by converting protein C to its active form (aPC). With its cofactor protein S, aPC inactivates factors Va and VIIIa regulating the functionality of the prothrombinase and tenase complexes, respectively.[11] aPC and protein S prevent coagulation reactions from spreading to healthy, uninjured vessel walls. Circulating antithrombin inhibits thrombin and factor Xa. Heparan sulfate, a heparin-like compound secreted by endothelial cells, exponentially accelerates antithrombin activity.[11] As described previously, TFPI plays an important role by regulating the initiation phase.[13] When these self-regulatory mechanisms are intact, the fibrin clot is limited to the vessel injury zone. However, disruptions in the system can result in hypercoagulability and thrombotic complications.[14]

The fibrinolytic system is responsible for blood clot dissolution.[15] Inactive plasminogen is converted by tissue plasminogen activator (tPA) to active plasmin, an enzyme that degrades fibrin mesh into soluble end products. Collectively, these soluble products are known as fibrin degradation products and include D-dimer, which is a marker of thrombosis used when diagnosing VTE.[15] The fibrinolytic system is regulated by a series of stimulatory and inhibitory substances (Fig. 38-2). Plasminogen activator inhibitor-1 inhibits tPA and α_2-antiplasmin inhibits plasmin activity. Impaired functioning of the fibrinolytic system has also been linked to hypercoagulability and thrombotic complications.[15]

Most venous thrombi begin in the leg(s). Thrombus isolated in calf veins is unlikely to break loose (embolize). Thrombus involving the popliteal and larger veins above the knee is more likely to embolize and travel through the right side of the heart and lodge in the pulmonary artery or one of its branches, causing PE, occlusion of blood flow to the lung, and impaired gas exchange. Without treatment, the affected lung becomes necrotic and oxygen delivery to other vital organs decreases, potentially resulting in fatal circulatory collapse.[1]

Inherited and Acquired Hypercoagulability Disorders

Disturbances in hemostatic regulation may result in inherited or acquired hypercoagulability.[14] aPC resistance increases the risk of VTE approximately threefold and is the most common inherited hypercoagulability disorder with a prevalence rate of 2.0% to 7.0% in White individuals.[14] aPC resistance most often results from a gene mutation that renders factor V resistant to degradation by aPC. This mutation is known as factor V Leiden.[14]

The prothrombin G20210A mutation also imparts about a threefold increased VTE risk and is the second most frequent inherited hypercoagulability disorder, occurring in about 2.0% to 4.0% of White individuals.[14] This mutation increases circulating prothrombin, enhancing thrombin generation potential.[10] Some patients inherit both factor V Leiden and prothrombin G20210A mutations, significantly increasing their lifetime VTE risk.[14]

Experts believe the lifetime risk associated with inherited protein C, protein S, and antithrombin deficiencies (present in <1% of the population) is high, perhaps sevenfold higher than patients without such disorders. Many patients with protein C, protein S, or antithrombin deficiency suffer VTE prior to age 60.[10]

Acquired disorders of hypercoagulability may result from cancer, the presence of antiphospholipid antibodies, or estrogen use. A strong link between cancer and thrombosis has long been recognized.[16] Tumor cells secrete procoagulant substances that activate the coagulation cascade, and patients with cancer often have suppressed protein C, protein S, and antithrombin levels. Cancer cells use thrombotic mechanisms to recruit a blood supply, metastasize, and create barriers against host defense mechanisms.[16]

Antiphospholipid antibodies are a heterogeneous group of antibodies targeting proteins that bind phospholipids.[10] These include antibodies that prolong phospholipid-based clotting assays, known as lupus anticoagulants, as well as anticardiolipin and β_2-glycoprotein (β_2-gp) I antibodies. Antiphospholipid antibodies are more common among patients with autoimmune disorders (eg, systemic lupus erythematosus and inflammatory bowel disease) compared to healthy individuals. The precise mechanism by which antiphospholipid antibodies provoke thrombosis remains uncertain. Contributing factors include complement activation, protein C and fibrinolysis inhibition, platelet activation, and increased TF expression.[10]

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

② The symptoms of DVT or PE are nonspecific and objective tests are required to confirm or exclude the diagnosis. Patients with DVT frequently present with unilateral leg pain and swelling. Postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, may also result in chronic lower extremity swelling, pain, tenderness, skin discoloration, and, in the most severe cases, ulceration. PE typically presents with chest pain, shortness of breath, tachypnea, and tachycardia, which in some cases may result in cardiopulmonary collapse.[17,18]

Because VTE can be debilitating or fatal, it is important to treat it quickly and aggressively. Conversely, because major bleeding induced by anticoagulant drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not a reasonable certainty. Assessment of the patient's status should focus on the search for risk factors in the patient's medical history (Table 38-1). Even in the presence of mild, seemingly inconsequential symptoms, VTE should be strongly suspected in those with multiple risk factors.[17]

Clinical assessment significantly improves the diagnostic accuracy of noninvasive tests such as compression ultrasound (CUS), computed tomography pulmonary angiography (CTPA), and D-dimer. Simple clinical assessment checklists such as the Wells score for DVT or PE or the revised Geneva score for PE can be used to determine if a patient is "likely" or "unlikely" to have DVT or PE (Figs. 38-6 and 38-7).[19] Patients with a likely probability of VTE have a >60% chance of VTE, compared with a <10% chance for patients with an unlikely probability.[20] In general, patients with an unlikely probability of VTE should first have their D-dimer tested. If the D-dimer result is below the defined cutoff point or reported as "negative," VTE is ruled out. D-dimer results above the cutoff point warrant appropriate diagnostic imaging (CUS for suspected DVT, or CTPA or ventilation/perfusion [V/Q] scanning for suspected PE).

D-dimer is a fibrin clot degradation product and levels are significantly elevated in patients with acute thrombosis. A variety of conditions other than VTE are associated with D-dimer elevations, including recent surgery or trauma, pregnancy, advanced age, and cancer; therefore, a positive D-dimer test is not conclusive evidence of VTE diagnosis. However, a *negative* D-dimer, for most assays defined as <500 ng/mL (mcg/L), can be useful in ruling out the diagnosis of VTE.[20] Appropriate use of D-dimer should include initial risk stratification using a validated clinical assessment tool.[20]

All patients with a likely probability of DVT should receive either proximal (popliteal, femoral, and iliac veins) or whole leg CUS. A normal whole leg ultrasound rules out DVT, whereas a normal proximal ultrasound requires whole leg ultrasound or repeat proximal ultrasound surveillance in 1 week. Patients with CUS indicating proximal DVT should receive anticoagulant treatment. Evidence of distal DVT (anterior and posterior tibial, peroneal, gastrocnemius veins) after whole leg ultrasound may be managed with anticoagulants or repeated ultrasound surveillance in 1 to 2 weeks to assess for propagation into the proximal deep veins of the leg (Fig. 38-6). Patients with a likely probability of PE should receive imaging with either CTPA or V/Q scan. A negative imaging result rules out PE, whereas a positive imaging result indicates need for anticoagulant treatment (Fig. 38-7).[17,19,20]

CLINICAL PRESENTATION: Deep Vein Thrombosis

General

DVT most commonly develops in patients with identifiable risk factors (see Table 38-1). Some may have asymptomatic disease.

Symptoms

The patient may complain of leg swelling, pain, or warmth. Symptoms are nonspecific and objective testing must be performed to establish the diagnosis

Signs

The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg. The patient may experience pain in the back of the knee when the examiner dorsiflexes the foot of the affected leg (Homan's sign).

Laboratory Tests

Serum concentration of D-dimer, a by-product of fibrin degradation, is nearly always elevated. A negative D-dimer (values <500 ng/mL [mcg/L]) combined with clinical decision rules are useful in ruling out the diagnosis of DVT.

Diagnostic Tests

Compression ultrasound is the most commonly used test to diagnose DVT. It is a noninvasive test that can visualize clot formation in veins of the legs. Coupled with a careful clinical assessment, it can rule in or out the diagnosis in the majority of cases. Venography is the gold standard for the diagnosis of DVT. However, it is an invasive test that involves the injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

CLINICAL PRESENTATION: Pulmonary Embolism

General

PE most commonly develops in patients with risk factors for VTE (see Table 38-1). Although many patients develop a symptomatic DVT prior to developing a PE, some do not. Patients may die suddenly from cardiogenic shock and circulatory collapse before effective treatment can be initiated.

Symptoms

The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitation. The patient may spit or cough up blood (hemoptysis). When PE is massive, the patient may complain of dizziness or light-headedness. Symptoms may be confused with myocardial infarction, requiring objective testing to establish the diagnosis.

Signs

The patient may have tachypnea, tachycardia, and appear diaphoretic. The patient's neck veins may be distended. In massive PE, the patient may appear cyanotic and become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate that the patient is hypoxic. In the worse cases, the patient may go into cardiogenic shock and die within minutes.

Laboratory Tests

Serum concentration of D-dimer, a by-product of fibrin degradation, is nearly always elevated. D-dimer values <500 ng/mL (mcg/L) combined with clinical decision rules are useful in ruling out the diagnosis of PE.

Diagnostic Tests

Computerized tomography pulmonary angiography (CTPA) is the most commonly used test to diagnose PE, but some centers still use the V/Q scan. A V/Q scan measures the distribution of blood and airflow in the lungs. When there is a large mismatch between blood and airflow in one area of the lung, there is a PE.

Pulmonary angiography is the gold standard for the diagnosis of PE. However, it is an invasive test that involves the injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality

PREVENTION OF VENOUS THROMBOEMBOLISM

Unfortunately, public awareness of the life-threatening nature of DVT and PE is lacking with many patients having little or no awareness of VTE symptoms or risk factors.[23] VTE awareness is substantially lower than for other disease states like stroke, heart attack, and breast cancer and there is a need to increase knowledge of the risks, signs, and symptoms of VTE.

Desired Outcomes

Prevention strategies in at-risk populations positively impact patient outcomes because VTE is potentially fatal and costly to treat.[26] Treatment of VTE is aimed at preventing thrombus extension and embolization, reducing recurrence risk, and preventing long-term complications such as the postthrombotic syndrome and CTPH. Carefully managed anticoagulant drug use is important to reduce the risk of bleeding associated with these agents.

General Approach to the Prevention of Venous Thromboembolism

Effective prophylaxis can reduce the risk of fatal PE in high-risk medical and surgical populations. Early ambulation is often sufficient for those at low risk of VTE.[27] Educational programs and clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.[28]

③ VTE continues to be a major risk for patient morbidity and mortality in hospitalized patients. Approximately half of all VTE occurs secondary to hospital admission or surgery, often occurring after hospital discharge. Effective VTE prophylaxis can prevent as much as 70% of VTE events related to hospitalization or surgery.[29–31] Safe and effective prophylaxis strategies must balance the risks for thromboembolism and bleeding. There is evidence that VTE prophylaxis is both underused in patients at high risk for VTE and overused in low-risk populations.[32] It is essential that patients are assessed for risks of VTE and bleeding (Table 38-2) prior to deciding whether VTE prophylaxis is appropriate. Distinct populations to consider for VTE prophylaxis include the medically ill and those undergoing surgery (Table 38-3). Each group has unique risk factors for VTE and bleeding to consider in determining an approach to VTE prophylaxis (Fig. 38-8).

TABLE 38-2

VTE and Bleeding Risk Assessment for Medically Ill Patients

VTE Risk Assessment		**Bleeding Risk Assessment**	
Characteristic	Points	Characteristic	Points
Reduced mobility	3	Renal failure (GFR 30-59 mL/min/1.73m^2)	1
Active cancer	3	Male	1
Previous VTE (excluding superficial thrombophlebitis)	3	Age 40-80	1.5
Known thrombophelia	3	Current cancer	2
Recent trauma or surgery (within 1 month)	2	Rheumatic disease	2
Age > 70 years	1	Central venous catheter	2
Heart or respiratory failure	1	Intensive or critical care unit stay	2.5
Acute myocardial infarction or ischemic stroke	1	Renal failure (GFR < 30 mL/min/1.73m^2)	2.5
Ongoing hormonal treatment	1	Hepatic failure (INR > 1.5)	2.5
Obesity (BMI > 30 kg/m^2)	1	Age ≥ 85	3.5
Active infection or rhematologic disorder	1	Platelet count < 50,000/mm^3 (50 × 10^9/L)	4
		Bleeding in previous 3 months	4
		Active gastroduodenal ulcer	4.5
4 points or greater is high risk for VTE		7 points or greater is high risk for major bleeding	

BMI, body mass index; GFR, glomerular filtration rate; INR, international normalized ratio. GFR expressed in units of mL/min/1.73m^2 is converted to SI units of mL/s/m^2 by multiplying by 0.0096. *Data from References 39,40.*

TABLE 38-3

Summary of Guideline Recommended Therapies Indicated for VTE Prophylaxis

		Orthopedic Surgery		
Indication	**Medically ill**	**TKA/THA**	**Hip fracture repair**	**Other major surgeries**[a]
Preferred agents	LMWH or fondaparinux	Aspirin or anticoagulants (DOACs favored; LMWH also supported)	LMWH or UFH	LMWH or UFH
Combined pharmacological and mechanical prophylaxis[b]	No	Yes	Yes	Yes
Extended duration pharmacological prophylaxis	No	Yes	Yes	Yes
Alternative pharmacologic agents	UFH or rivaroxaban	Fondaparinux, low-dose UFH, or warfarin	Fondaparinux or warfarin	n/a
Alternative mechanical prophylaxis in high bleeding risk	IPC	IPC and/or compression stockings	IPC and/or compression stockings	IPC and/or compression stockings

THA, total hip arthroplasty; TKA, total knee arthroplasty; LMWH, low-molecular weight heparin; DOACs, direct-acting oral anticoagulants; UFH, unfractionated heparin; IPC, intermittent pneumatic compression

[a] Excludes prostate resection, prostatectomy, and neurosurgery;

[b] Combination of aspirin or anticoagulation plus IPC or graduated compression stockings

Data from References 2,3,34,37.

Nonpharmacologic Therapy

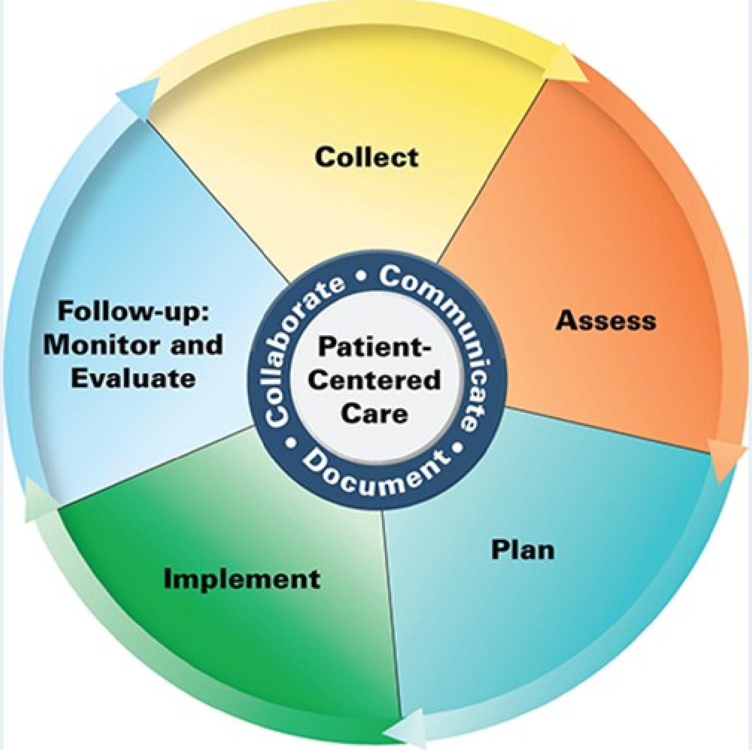
Graduated compression stockings and intermittent pneumatic compression (IPC) devices prevent VTE by increasing the velocity of lower extremity venous blood flow through graded pressure application. IPC devices utilize a series of cuffs wrapped around the patient's legs that inflate in continuous 1- to 2-minute cycles from the ankles to the knees or thighs. IPC devices should be worn at least 18 hr/day for optimal effectiveness.

Graduated compression stockings do not reliably reduce VTE in medically ill patients.[33] However, they reduce the incidence of VTE (including asymptomatic and distal DVT) by approximately 65% when used after orthopedic surgery, cardiac surgery, gynecologic surgery, or neurosurgery.[34] IPC reduces the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery.[34] Both modalities can be used in combination with anticoagulation in appropriate settings (see below) to maximize VTE prevention.[35]

Mechanical methods do not increase bleeding risk, which makes them attractive for VTE prophylaxis following surgery, especially in patients with contraindications to anticoagulation. However, they are not risk-free, as discomfort, skin breakdown, and ulceration can occur.[33]

Inferior vena cava (IVC) filters can provide short-term protection against PE in very high-risk patients by blocking embolization of thrombus formed below the filter.[36] Percutaneous insertion of an IVC filter is a minimally invasive procedure performed using fluoroscopic imaging to verify placement. Frequently "retrievable" IVC filters are never retrieved, increasing the risk for long-term complications such as DVT, filter migration, IVC occlusion, and insertion site thrombosis.[34] Therefore, IVC filters should be reserved for patients at the highest VTE risk in whom other prophylactic strategies cannot be used. The data supporting the use of IVC filters for primary VTE prophylaxis in patients at high risk of bleeding is very weak.[2] Routine use of IVC filters is not recommended and their potential role in high bleeding risk patients remains to be determined.[2] IVC filters should be removed when VTE risk has passed or when anticoagulation is no longer contraindicated.[36]

Patient Care Process for the Prevention of VTE



Collect
Assess

Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, active cancer, pregnant)
- Patient history (past medical [eg, bleeding history], family, social—dietary habits including intake of vitamin K-containing foods [see Table 38-12], tobacco/ethanol use)
- Current medications including over-the-counter aspirin and NSAID use; prior anticoagulant medication use
- Objective data
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), O_2-saturation, height, weight
  - Labs (eg, hemoglobin [Hgb], serum creatinine [Scr], platelets, activated partial thromboplastin time [aPTT], prothrombin time [PT])

Assess

- Presence of VTE risk factors (see Table 38-1); consider using risk stratification tools appropriate for medical or surgical patients (see Table 38-2)
- Presence of active bleeding and/or bleeding risk factors (see Table 38-10)
- Presence of medications that increase VTE risk (eg, estrogen)
- Presence of contraindications to anticoagulation therapy
- Ability/willingness to self-inject LMWH or fondaparinux if extended parenteral therapy is being considered
- Ability/willingness to pay for various anticoagulation therapy options if extended therapy is being considered
- Ability/willingness to obtain appropriate laboratory monitoring if extended therapy is being considered (eg, INR [international normalized ratio] for warfarin)

Plan[*]

- Drug therapy regimen including specific anticoagulant(s) or reversal agent(s), dose, route, frequency, and duration (see Fig. 38-9)
- Monitoring parameters including effectiveness (eg, INR results, signs and symptoms of VTE), safety (bleeding, platelet count [heparin]), and timing of assessments
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy; see Table 38-5)
- Self-monitoring for VTE symptoms, occurrence of bleeding, when to seek emergency medical attention

Implement

- Ensure appropriate VTE prevention is initiated based on patient-specific VTE/bleeding risk
- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence if extended therapy being considered
- Schedule follow-up (eg, INR tests [warfarin], bleeding assessment, duration of therapy assessment)

Follow-up: Monitor and Evaluate

- Occurrence of VTE symptoms (eg, shortness of breath, chest pain, leg or arm swelling, redness, pain)
- Presence of adverse drug reactions (eg, bleeding, gastrointestinal upset [dabigatran only], HIT [heparin-induced thrombocytopenia])
- INR results (adjust warfarin dose as needed to keep within target range)
- Patient adherence to the treatment plan if extended therapy
- Inquire whether the patient is ambulatory and/or weight-bearing (following orthopedic surgery)

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

Pharmacologic Therapy

Pharmacologic options for preventing VTE have been extensively evaluated in randomized clinical trials and significantly reduce the risk of VTE following hip and knee replacement, hip fracture repair, general surgery, myocardial infarction, ischemic stroke, and in selected hospitalized medical patients.[33,34,37] The optimal agent and dose for VTE prevention must be based on an assessment of VTE and bleeding risk, as well as cost and availability. In general, pharmacologic therapy is preferred over mechanical interventions in patients without active bleeding or high risk for bleeding. Pharmacologic prophylaxis options include UFH, LMWH, DOACs, aspirin, and warfarin. Each can be used safely and effectively given the appropriate clinical scenario.

Medical Patients

Low-dose UFH, LMWH, and fondaparinux all reduce symptomatic VTE and fatal PE among high-risk medical patients.[2] Rivaroxaban is as effective as enoxaparin for VTE prophylaxis during hospitalization and is approved for VTE prophylaxis in medically ill patients including after hospital discharge for a total duration of 39 days.[38] However, routine use of extended duration prophylaxis beyond hospital discharge is not supported by guidelines.[3]

Hospitalized and acutely ill medical patients at high VTE risk and low bleeding risk should receive pharmacologic prophylaxis with low-dose UFH, LMWH, fondaparinux, or rivaroxaban during hospitalization or until fully ambulatory. The use of extended prophylaxis beyond hospital discharge reduces the risk of VTE but with a comparable increase in bleeding and is not recommended in the medically ill population.[3] LMWH or fondaparinux are preferred to low-dose UFH or DOACs for VTE prophylaxis in medically ill inpatients. Routine pharmacologic prophylaxis is not warranted in low-

VTE-risk medical patients.

Several risk assessment models have been developed to identify hospitalized and critically ill patients at high VTE risk likely to benefit from thromboprophylaxis. The Padua Prediction Score is a prospectively validated VTE risk assessment tool for hospitalized medical patients.[39] Among high-risk patients (score ≥4 points) not receiving prophylaxis, VTE occurred in 11.0% within 90 days compared with just 0.3% of low-risk patients. Bleeding risk can be estimated using various risk stratification tools such as the IMPROVE bleeding score.[40] An IMPROVE score of ≥7 points was associated with a major bleeding risk of 4.1%. Mechanical prophylaxis is preferred over anticoagulation therapy in medical patients at high bleeding risk.[2] Patients with severe hepatic insufficiency are not adequately protected from VTE even if baseline INR is elevated. This population is particularly challenging as they are at risk for VTE without prophylaxis and bleeding with pharmacologic prophylaxis.[41,42]

Table 38-2 summarizes a scoring system for VTE risk and bleeding assessment in medically ill patients. Figure 38-8 outlines a general approach to deciding on VTE prophylaxis once VTE and bleeding risk scores have been estimated.

Surgical Patients

General recommendations for reducing perioperative VTE risk include using regional rather than general anesthesia, whenever possible, and having patients ambulate as soon as it is safe to do so.[17]

Risk stratification tools (e.g. Caprini score) also exist for estimating VTE risk in surgical populations. However, current guidelines provide recommendations according to the type of surgery rather than based on specific risk assessment models.[2] Most patients having general, gynecologic, cardiac, and vascular surgery should receive pharmacologic prophylaxis with LMWH or low-dose UFH to prevent VTE. Patients unable to receive pharmacologic prophylaxis should use IPCs or compression stockings.[2] Combination of pharmacologic and mechanical VTE prevention methods have the potential to reduce the risk for VTE as well as mortality compared to pharmacologic prophylaxis alone. The addition of mechanical prophylaxis is generally well tolerated and should be particularly advantageous to patients with additional risk factors for VTE.[2]

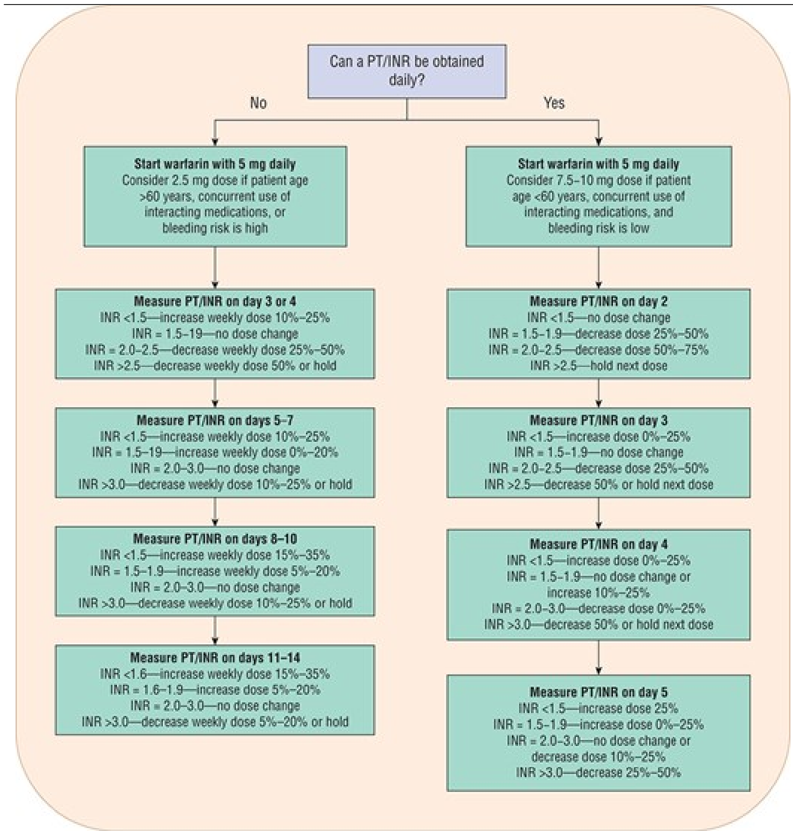
There are a few surgery types excluded from the general recommendations above. Uncomplicated laparoscopic cholecystectomy does not routinely require VTE prophylaxis unless the patient has additional VTE risk factors, such as a history of VTE, hypercoagulability, or active cancer. Patients undergoing surgery that involves high bleeding risk (eg, urologic procedures) or where small amounts of bleeding can result is substantial morbidity (eg, intracranial or spinal surgery) are typically managed with IPCs rather than pharmacologic prophylaxis.[2]

Total joint arthroplasty has historically been associated with very high postoperative VTE risk.[37] Pharmacologic agents for VTE prevention following joint replacement surgery include aspirin, adjusted-dose warfarin, low-dose UFH, LMWH, fondaparinux, dabigatran, apixaban, and rivaroxaban for a minimum of 10 days postsurgery.[37] Optimal timing of anticoagulation initiation is between 6 and 12 hours postop. Earlier initiation increases bleeding risk up to fivefold.[37]Extended duration prophylaxis is also recommended to prevent delayed VTE up to 35 days postoperatively.

Warfarin remains a commonly prescribed agent for VTE prevention after total joint arthroplasty due to low acquisition cost, oral administration, and delayed onset, potentially reducing the risk of early postoperative bleeding (see Fig. 38-9).[43] The optimal target INR during warfarin prophylaxis is not clear. It is common for INR targets lower than the standard range of 2 to 3 to be employed as the American Academy of Orthopaedic Surgery guidelines do not recommend a specific INR target.[37,44]

FIGURE 38-9

Initiation of warfarin therapy.



Can a PT/INR be obtained daily?
No
Yes
Start warfarin with 5 mg daily
Consider 2.5 mg dose if patient age >60 years, concurrent use of interacting medications, or bleeding risk is high
Start warfarin with 5 mg daily
Consider 7.5–10 mg dose if patient age <60 years, concurrent use of interacting medications, and bleeding risk is low
Measure PT/INR on day 3 or 4
INR <1.5—increase weekly dose 10%–25%
INR = 1.5–19—no dose change
INR = 2.0–2.5—decrease weekly dose 25%–50%
INR >2.5—decrease weekly dose 50% or hold
Measure PT/INR on day 2
INR <1.5—no dose change
INR = 1.5–1.9—decrease dose 25%–50%
INR = 2.0–2.5—decrease dose 50%–75%
INR >2.5—hold next dose
Measure PT/INR on days 5–7
INR <1.5—increase weekly dose 10%–25%
INR = 1.5–19—increase weekly dose 0%–20%
INR = 2.0–3.0—no dose change
INR >3.0—decrease weekly dose 10%–25% or hold
Measure PT/INR on day 3
INR <1.5—increase dose 0%–25%
INR = 1.5–1.9—no dose change
INR = 2.0–2.5—decrease dose 25%–50%
INR >2.5—decrease 50% or hold next dose
Measure PT/INR on days 8–10
INR <1.5—increase weekly dose 15%–35%
INR = 1.5–1.9—increase weekly dose 5%–20%
INR = 2.0–3.0—no dose change
INR >3.0—decrease weekly dose 10%–25% or hold
Measure PT/INR on day 4
INR <1.5—increase dose 0%–25%
INR = 1.5–1.9—no dose change or increase 10%–25%
INR = 2.0–3.0—decrease dose 0%–25%
INR >3.0—decrease 50% or hold next dose
Measure PT/INR on days 11–14
INR <1.6—increase weekly dose 15%–35%
INR = 1.6–1.9—increase dose 5%–20%
INR = 2.0–3.0—no dose change
INR >3.0—decrease weekly dose 5%–20% or hold
Measure PT/INR on day 5
INR <1.5—increase dose 25%
INR = 1.5–1.9—increase dose 0%–25%
INR = 2.0–3.0—no dose change or decrease dose 10%–25%
INR >3.0—decrease 25%–50%

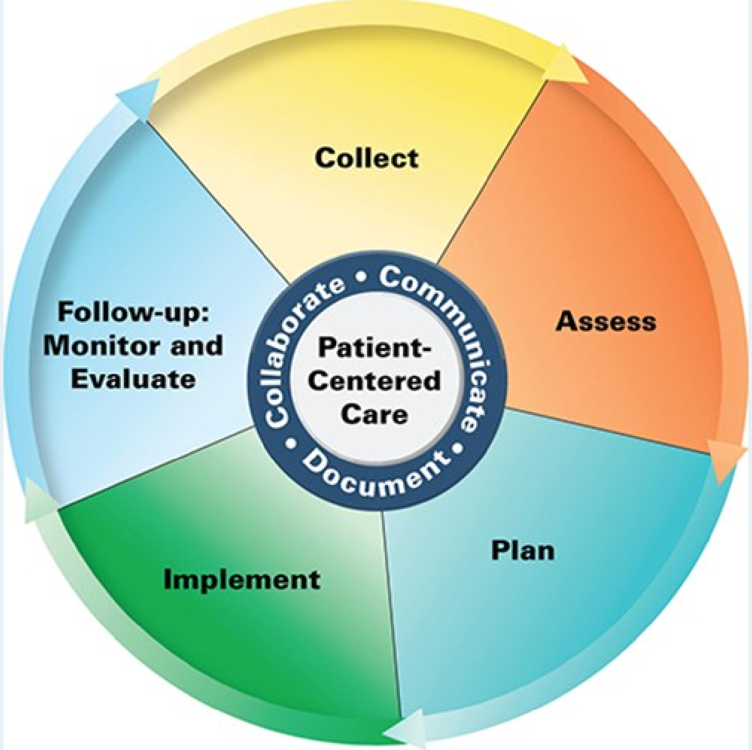
DOACs offer convenient oral administration and fixed dosing without the need for routine coagulation testing. The safety and efficacy of DOACs are similar to enoxaparin after total joint replacement, but studies after hip fracture surgery are lacking.[37] The American Society of Hematology recommends DOACs over other anticoagulants for VTE prophylaxis after total joint replacement.[2] If a DOAC is not available or contraindicated, LMWHs are generally preferred over UFH or warfarin (see Table 38-3 for VTE prophylaxis summary). If aspirin is used, a two-tiered approach might be considered where aspirin is the default option for patients who have not additional VTE risk factors and DOACs, warfarin, or LMWH reserved for patients with additional VTE risk factors (e.g. obesity, active cancer, history of VTE). Finally, a short course (eg, 5 days) of DOAC therapy followed by aspirin provides an early anticoagulant effect and may optimally balance the use of an anticoagulant to prevent early postoperative thrombosis when the risk is highest, and a low-cost oral option (aspirin) that can be easily administered after hospital discharge.[45]

Duration of Therapy

VTE incidence is relatively high in the month following hospital discharge among patients undergoing lower extremity orthopedic procedures; therefore, extended prophylaxis appears to be beneficial.[2] Most clinical trials support the use of antithrombotic prophylaxis for 15 to 42 days following total knee or hip replacement surgery.[2] Optimal VTE prophylaxis duration following other major surgeries is not well established. Prophylaxis should be given throughout the period of increased VTE risk. Guidelines support extended VTE prophylaxis for up to 42 days after major surgery.[2] However, it may be reasonable to forego extended prophylaxis after less extensive procedures where patients are ambulatory and other risk factors are no longer present.

PATIENT CARE PROCESS

Patient Care Process for the Treatment of VTE



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient history (past medical, family, social—dietary habits including intake of vitamin K-containing foods (see Table 38-12), tobacco/ethanol use)
- Current medications including over-the-coutner aspirin/NSAID use; prior anticoagulant medication use
- Objective data
    - BP, HR, RR, O_2-saturation, height, weight
    - Labs (eg, Hgb, Scr, platelets, aPTT, PT)
    - Do NOT order hypercoagulability tests
    - Objective confirmation of VTE (see Figs. 38-6 and 38-7)

Assess

- For PE, hemodynamic instability (eg, SBP <90 mm Hg, HR >110 bpm, O_2-sat <90% [0.90])
- Presence of active bleeding and/or bleeding risk factors (see Table 38-10)
- Presence of VTE provoking factors (eg, recent surgery, plaster casting of lower extremity, indwelling catheter, cancer, pregnancy, estrogen use, prolonged immobility, recent hospitalization)
- Ability/willingness to self-inject LMWH/fondaparinux
- Ability/willingness to pay for various anticoagulation therapy options

- Ability/willingness to obtain appropriate laboratory monitoring (eg, INR for warfarin)
- Emotional status (eg, presence of anxiety, depression)

Plan[*]

- Drug therapy regimen including specific anticoagulant(s), dose, route, frequency, and duration; (see Figs. 38-8–38-11, Tables 38-4 to 38-6)
- Monitoring parameters including effectiveness (eg, INR results, pain control, limb swelling, shortness of breath), safety (bleeding, VTE recurrence), and timing of assessments
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, invasive procedures, drug therapy; see Table 38-5)
- Self-monitoring for resolution of VTE symptoms, the occurrence of bleeding, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, thrombosis specialist, behavioral health, dietician)

Implement

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, INR tests [warfarin], Scr [DOACs], adherence assessment, bleeding risk assessment, duration of therapy assessment)

Follow-up: Monitor and Evaluate

- Resolution of VTE symptoms (eg, shortness of breath, chest pain, swelling, redness, pain)
- Presence of adverse drug reactions (eg, bleeding, GI upset [dabigatran])
- INR results (adjust warfarin dose as needed to keep between 2 and 3)
- Patient adherence to treatment plan using multiple sources of information
- Duration of therapy after 90 days

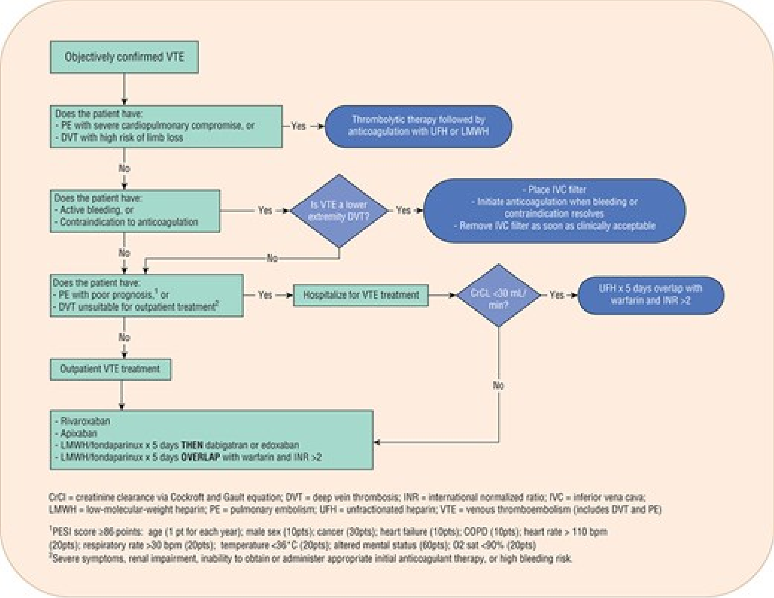
TREATMENT OF VENOUS THROMBOEMBOLISM

General Approach to the Treatment of Venous Thromboembolism

Anticoagulation therapies remain the mainstay of VTE treatment. DVT and PE are manifestations of the same disease process and are treated similarly (Figs. 38-10 and 38-11). Before prescribing anticoagulation therapy for VTE treatment, establishing an accurate diagnosis is imperative to prevent unnecessary bleeding risk and expense to the patient.[18] Patients with a likely VTE probability (Figs. 38-6 and 38-7) may need rapid-onset anticoagulation therapy while awaiting diagnostic testing results. However, patients with unlikely VTE probability may only need rapid-onset anticoagulation in the setting of a positive D-dimer with anticipated delays in diagnostic testing exceeding 4 hours.[17]

FIGURE 38-10

Decision algorithm: Acute treatment of VTE. (CrCl, creatinine clearance via Cockroft and Gault equation; VTE, venous thromboembolism [includes DVT and PE].) (*Data from References 37,39.*)



Objectively confirmed VTE
Does the patient have:
- PE with severe cardiopulmonary compromise, or
- DVT with high risk of limb loss
Yes
Thrombolytic therapy followed by anticoagulation with UFH or LMWH
No
Does the patient have:
- Active bleeding, or
- Contraindication to anticoagulation
Yes
Is VTE a lower extremity DVT?
Yes
- Place IVC filter
- Initiate anticoagulation when bleeding or contraindication resolves
- Remove IVC filter as soon as clinically acceptable
No
No
Does the patient have:
- PE with poor prognosis,1 or
- DVT unsuitable for outpatient treatment2
Yes
Hospitalize for VTE treatment
CrCL <30 mL/min?
Yes
UFH x 5 days overlap with warfarin and INR >2
No
No
Outpatient VTE treatment
- Rivaroxaban
- Apixaban
- LMWH/fondaparinux x 5 days THEN dabigatran or edoxaban
- LMWH/fondaparinux x 5 days OVERLAP with warfarin and INR >2
CrCl = creatinine clearance via Cockroft and Gault equation; DVT = deep vein thrombosis; INR = international normalized ratio; IVC = inferior vena cava; LMWH = low-molecular-weight heparin; PE = pulmonary embolism; UFH = unfractionated heparin; VTE = venous thromboembolism (includes DVT and PE)
1PESI score ≥86 points: age (1 pt for each year); male sex (10pts); cancer (30pts); heart failure (10pts); COPD (10pts); heart rate > 110 bpm (20pts); respiratory rate >30 bpm (20pts); temperature <36°C (20pts); altered mental status (60pts); O2 sat <90% (20pts)
2Severe symptoms, renal impairment, inability to obtain or administer appropriate initial anticoagulant therapy, or high bleeding risk.

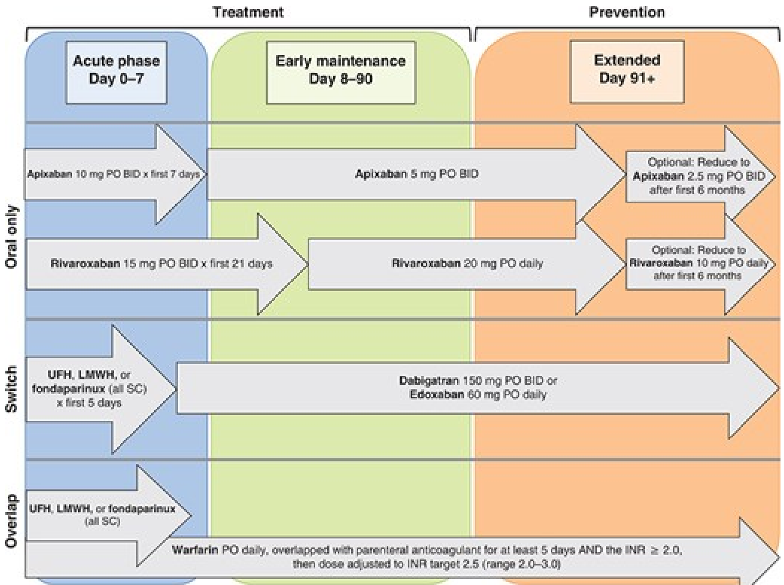
FIGURE 38-11

Overview of VTE treatment strategies: Acute, early maintenance, and extended treatment phases.



Treatment
Prevention
Acute phase Day 0–7
Early maintenance Day 8–90
Extended Day 91+
Oral only
Apixaban 10 mg PO BID x first 7 days
Apixaban 5 mg PO BID
Optional: Reduce to Apixaban 2.5 mg PO BID after first 6 months
Rivaroxaban 15 mg PO BID x first 21 days
Rivaroxaban 20 mg PO daily
Optional: Reduce to Rivaroxaban 10 mg PO daily after first 6 months
Switch
UFH, LMWH, or fondaparinux (all SC) x first 5 days
Dabigatran 150 mg PO BID or Edoxaban 60 mg PO daily
Overlap
UFH, LMWH, or fondaparinux (all SC)
Warfarin PO daily, overlapped with parenteral anticoagulant for at least 5 days AND the INR ≥ 2.0, then dose adjusted to INR target 2.5 (range 2.0–3.0)

Strict bed rest was traditionally recommended following acute DVT based on the assumption that leg movement would dislodge the clot, resulting in PE. However, ambulation in conjunction with graduated compression stockings results in a faster reduction of pain and swelling with no apparent increase in embolization rate. Patients should be encouraged to ambulate as much as symptoms permit. If ambulation increases pain and swelling, the patient should be instructed to lie down and elevate the affected leg until symptoms subside.

IVC filters have a limited role in the management of acute VTE and should only be used when anticoagulants are contraindicated due to active bleeding.[21] As soon as the bleeding resolves, patients should receive a conventional course of anticoagulant therapy and have the filter removed within 90 to 120 days of implantation.[17,18,36] In life- or limb-threatening circumstances, elimination of the obstructing thrombus may be warranted and the use of thrombolysis or thrombectomy considered.[18,46]

④ ⑦ Once the diagnosis of VTE has been objectively confirmed (see details regarding Clinical Presentation and Diagnosis above), anticoagulant therapy with a rapid-acting anticoagulant should be instituted as soon as possible. Available anticoagulants can be administered in the outpatient setting in most patients with DVT and in carefully selected hemodynamically stable patients with PE. Given the predictable response and reduced need for laboratory monitoring with LMWH and DOACs, stable patients with DVT or PE who have normal vital signs, low bleeding risk, and no other uncontrolled comorbid conditions requiring hospitalization can be discharged early or treated entirely on an outpatient basis (Table 38-4).[47] Not all patients are appropriate candidates for outpatient VTE treatment. At a minimum, patients must be reliable or have adequate caregiver support and be willing and active participants in outpatient VTE management. Important patient education aspects for outpatient VTE treatment are summarized in Table 38-5. Hemodynamically unstable patients with PE should be admitted for anticoagulation therapy initiation. The decision to initiate outpatient therapy should be based on institutional resources and patient-specific variables.[46,48]

TABLE 38-4

Outpatient Treatment Suggestions for DVT and PE

- Inclusion: Patients with objectively diagnosed VTE
- Exclusion: Hemodynamically unstable, arterial thromboembolism or patients currently receiving dialysis, actively bleeding, recent (within 2 weeks) major surgery/trauma, or other severe uncompensated comorbid conditions
- Suggested procedure may vary depending on the patient's clinical condition
- Confirm diagnosis of VTE by objective testing

Day 1

- Baseline laboratory evaluation
    - INR—if use of warfarin anticipated
    - SCr
    - Complete blood count (CBC) with platelets
- Medication—see Fig. 38-11
- Patient education
    - Clinical pharmacy/nursing
        - Educate patient regarding the importance of proper monitoring of anticoagulation therapy (if applicable) and warning signs that should prompt additional medical evaluation; document activities in the medical record
        - If applicable, teach patient how to self-administer LMWH/fondaparinux (if patient or family member unwilling or unable to self-administer injection, visiting nurse services should be arranged or consider single oral anticoagulant approach); initial injection should be administered in the medical office or hospital
        - Instruct patient regarding local therapy: elevation of affected extremity, localized heat, anti-embolic exercises (flexion–extension of ankle for lower extremity VTE, or hand squeezing–relaxation for upper extremity VTE)
    - Dispensing pharmacy
        - Reinforce patient education regarding indication, use, monitoring, adverse drug reactions, and drug interactions with antithrombotic therapy
        - Screen patient's pharmacy profile for potential drug-drug interactions with anticoagulation therapy
        - Dispense anticoagulant therapy
        - Verify anticoagulation service enrollment

Days 3-4

- Laboratory evaluation if on warfarin: check INR
- Assess for symptoms of pulmonary embolism or bleeding
- Medications: continue anticoagulant medication(s) as directed

- Anticoagulation service
    - If on warfarin interpret results of INR and adjust dose of warfarin to achieve a INR of 2 to 3
    - Patient activity: continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated
    - Document activities in medical record

Day 5

- Laboratory evaluation if on warfarin: check INR
- Assess for symptoms of bleeding or pulmonary embolism
- Medications: continue anticoagulant medication(s) as directed
- Anticoagulation service
    - If on warfarin interpret results of INR and adjust dose of warfarin to achieve a INR of 2 to 3 (stop LMWH if INR ≥2.0)
    - Patient activity: no restriction; if pain increases, contact primary care provider
    - Document activities in medical record

Day 6 (Dabigatran or Edoxaban)

- Medications: transition from parenteral to oral medication
- Assess for symptoms of bleeding or pulmonary embolism
- Anticoagulation service
    - Verify adherence, affordability, and tolerability of oral medication
    - Patient activity: no restriction; if pain increases, contact primary care provider
    - Review key education points (eg, keep in original container [dabigatran])
    - Document activities in medical record

Day 8 (Apixaban)

- Medications: decrease apixaban dose
- Anticoagulation service
    - Patient activity: no restrictions; if pain increases contact primary care provider
    - Verify adherence, affordability, and tolerability of oral medication
    - Document activities in medical record

Day 22 (Rivaroxaban)

- Medications: decrease rivaroxaban dose
- Anticoagulation service
    - Verify adherence, affordability, and tolerability of oral medication
    - Patient activity: no restriction; if pain increases, contact primary care provider
    - Review key education points (eg, take with food [rivaroxaban])
    - Document activities in medical record

TABLE 38-5

Patient Education for Outpatient VTETherapy

General Information Regarding VTE and the Goals of Treatment

- Anticoagulant medications (injections and warfarin tablets, injections and dabigatran or edoxaban, or rivaroxaban or apixaban) have been prescribed to prevent your blood clot from growing larger so that the body can begin to dissolve the clot.
- Your body may be able to completely dissolve the clot, but in some cases, the clot never goes completely away; even with adequate anticoagulation therapy, some people will have chronic pain and swelling in the affected limb; people who have had one clot are at increased risk of having future clots.
- Warfarin tablets take several days to begin to work, so at first, LMWH or fondaparinux injections and warfarin tablets are used together.
- When the warfarin has become effective, you will be able to stop the LMWH or fondaparinux injections; you will continue to take warfarin tablets for 3 months or longer to prevent blood clots from returning.
- It is important for you to administer your LMWH or fondaparinux and warfarin exactly as directed.
- It is important not to use LMWH at the same time as dabigatran or edoxaban—first use LMWH then switch to dabigatran or edoxaban.

Subcutaneous Injection Technique (If Needed)

- You must learn to give yourself an injection of LMWH or fondaparinux under the skin; alternatively, you may have a family member or visiting nurse give it to you.
- If your LMWH or fondaparinux syringes were filled by the manufacturer, they can be stored at room temperature; if your syringes were filled by the pharmacy, they should be stored in the refrigerator; if you were instructed to fill your own syringes, you should prepare the syringe immediately prior to injecting its contents.
- If you see a bubble in the syringe, do not try to get it out; you may accidentally squirt out part of your dose.
- Choose an injection site on your abdomen; clean the area with alcohol, and then position an uncapped syringe at a 90° angle; pinch the skin, stick the needle in as far as it will go, and gently but firmly push the plunger down; this will inject the medicine into the skin; when all the medication has been injected, remove the needle and dispose of it in an appropriate container.
- You will likely experience a burning sensation when the medication is injected; this will go away after a few minutes.
- Rotate injection sites from side to side; do not inject into the same site more than once; avoid the area around your navel; do not inject into any bruises.

Blood Test Monitoring

- If you are taking warfarin, regular blood tests are required to make sure your medication is working properly.
- The PT tells how quickly your blood forms a clot; it is used to tell how well warfarin is working.
- The INR is a way to standardize the PT between laboratories; your goal INR range is between 2 and 3; if your INR is less than 2, you are at higher risk for clotting; if your INR is greater than 3, you are at higher risk for bleeding; your dose of warfarin will be adjusted based on the results of this test.
- If you are taking LMWH, fondaparinux, dabigatran, edoxaban, rivaroxaban, or apixaban you need to have a blood test to determine how well your kidneys are working.

Warfarin Information

- Each strength of warfarin has a unique color; each time you refill your prescription, make sure your new tablets are the same color as the ones you have been taking; if not, ask your pharmacist why.
- Warfarin should be taken at approximately the same time each day.
- The most common and serious adverse drug reaction of warfarin is bleeding; you should be careful to avoid situations or activities that increase your risk of injury; apply direct pressure to control bleeding from superficial cuts.
- Warfarin has many drug interactions; always check with your provider before taking any new medications (including nonprescription medications and dietary supplements).
- Foods rich in vitamin K (dark green leafy vegetables, etc.) may interfere with warfarin; do not avoid foods rich in vitamin K, but try to maintain consistent dietary habits.
- Alcohol can increase your risk for bleeding and interfere with warfarin therapy; drink alcohol in moderation (one to two drinks per day); avoid binge drinking.
- If you need to have a surgery or diagnostic procedure, talk to your provider to make a plan for how to take your anticoagulant medication before and after the procedure. Do not stop taking your anticoagulant medication without first talking to your provider.

Dabigatran, Edoxaban, Rivaroxaban, and Apixaban Information

- Take rivaroxaban 15- or 20-mg doses with food to make sure the medication is well absorbed from your stomach.
- It is very important that you take each dose of your medication. These medications leave your body within hours; so missing a dose of medication may place you at a higher risk of blood clots.
- If you need to have a surgery or procedure, talk to your provider to make a plan for how to take your anticoagulant medication before and after the procedure. Do not stop taking your anticoagulant medication without first talking to your provider.
- There are a few drug interactions with dabigatran, edoxaban, rivaroxaban, and apixaban; always check with your provider before taking any new medications (including nonprescription medications and dietary supplements).

Contact Your Provider If You Experience

- Prolonged bleeding from a cut or scrape
- Blood in your urine
- Blood in your stool
- Prolonged nose bleeding (longer than 30 minutes)
- Increased swelling or pain where the blood clot was

Go to the Emergency Department If You Experience

- Sudden onset of shortness of breath
- Chest pain
- Coughing up blood
- Black tarry-appearing stool
- Severe headache of sudden onset
- Drooping of one side of your face
- Weakness in one of your arms
- Slurred speech

⑧ The appropriate initial duration of anticoagulation therapy to effectively treat an acute first episode of VTE for all patients is 3 months.[47] To prevent new VTE episodes not directly related to the preceding episode, continuing anticoagulation therapy may be required.[1] Individually tailoring anticoagulation therapy duration therapy beyond 3 months requires careful consideration of the circumstances surrounding the initial thromboembolic event, the presence of ongoing thromboembolic risk factors, bleeding risk, and patient preference.[47]

The most important considerations in determining recurrent VTE risk are whether the initial thrombotic event was associated with a major transient or reversible risk factor (eg, surgery, plaster cast leg immobilization, or hospitalization in the month prior to VTE) and the presence of active cancer.[47] The estimated cumulative risk of recurrent VTE after stopping anticoagulant therapy for VTE provoked by surgery is 1% after 1 year and 3% after 5 years. The cumulative risk of recurrent VTE provoked by a nonsurgical reversible risk factor is higher, 5% and 15% after 1 and 5 years, respectively. Three months of anticoagulation therapy is recommended in these situations.[18] Patients with a first unprovoked (idiopathic) VTE have approximately 10% recurrence risk in the first year and approximately 30% and 50% over 5 and 10 years, respectively. These patients should be considered for extended anticoagulation therapy when feasible.[47] With extended therapy, anticoagulation continues beyond 3 months, stopping only if bleeding risk increases substantially or change in patient preference for anticoagulation changes.[47] For patients with a second idiopathic VTE episode, extended anticoagulation is recommended.[47] Anticoagulation is rarely stopped in patients with VTE and active cancer because of the high recurrence risk.[47] Factors that may lead to the decision to stop anticoagulation therapy after 3 months include nonadherence with therapy, initial clot isolated in calf veins (even if idiopathic), moderate-to-high bleeding risk, or patient preference.[47]

Important risk factors for bleeding include age >75 years, previous noncardioembolic stroke, history of gastrointestinal bleeding, renal or hepatic impairment, anemia, thrombocytopenia, concurrent antiplatelet use (avoid if possible), nonadherence, poor anticoagulant control (for patients on warfarin), serious acute or chronic illness, and the presence of structural lesions (eg, tumor, recent surgery) that could bleed. One to two bleeding risk factors suggest moderate bleeding risk while three or more suggest high bleeding risk.[18]

Various risk prediction rules aimed at identifying patients with very low recurrence risk after a first idiopathic VTE have evaluated whether the safe withdrawal of anticoagulation therapy may be possible after 3 months. Some factors that may predict lower recurrence risk include female sex, low D-dimer levels 1 month after stopping anticoagulation therapy, absence of residual clot on ultrasound, absence of hereditary and acquired thrombophilia, and absence of the postthrombotic syndrome. Risk assessment derived from combining several independent recurrence risk factors has also been investigated.[18] Further validation is needed before any one factor or prediction rule using a combination of factors can justify stopping anticoagulation. The decision to continue extended anticoagulation therapy should be reassessed periodically. Patients should be involved in any decision to continue therapy with consideration given to long-term prognosis, risk of bleeding, ability to adhere to anticoagulation therapy instructions, financial resources, lifestyle, and quality of life.[18] When anticoagulation therapy is stopped, there is a similar risk of recurrence whether patients have been treated for 3 months or longer.[47]

Patients with VTE are often tested for hereditary and acquired hypercoagulable states (thrombophilia). The available evidence does not support a strong association between genetically transmitted thrombophilia (especially factor V Leiden and prothrombin G20210A) and higher recurrent VTE rates.[10] For this reason, routine testing for thrombophilia is not recommended.[17]

For patients with proximal DVT, wearing graduated compression stockings does not reduce the risk of developing the postthrombotic syndrome.[49] However, for patients with persistent leg pain and swelling, graduated compression stockings can be suggested for symptomatic relief.

Pharmacologic Therapy

The anticoagulant drugs used to treat VTE are the same as those used for VTE prevention. However, there are important differences in the approach to VTE treatment regarding the doses used and duration of therapy.

Direct Oral Anticoagulants

Clinical trials have demonstrated that single-drug therapy with rivaroxaban or apixaban produces similar rates of recurrent VTE when compared to the traditional approach of initiating warfarin overlapped with enoxaparin for both acute DVT and PE.[50–52] The rate of major bleeding was lower with rivaroxaban in the PE trial,[51] but not in the DVT trial.[52] Apixaban was associated with significantly fewer major bleeding episodes than traditional therapy.[50] Both drugs are initiated with a higher dose and subsequently reduced to a maintenance dose (Fig. 38-11). Patients with CrCl <25 to 30 mL/min (0.42-0.5 mL/s), active cancer, and those requiring thrombolytic therapy were excluded from these clinical trials.[50–52] Subsequent studies have shown that edoxaban and rivaroxaban can be used in cancer patients with VTE and prescribing information for apixaban contains no restrictions based on creatinine clearance.[53,54] Replacing the effective but cumbersome combination warfarin overlapped with an injectable anticoagulant with a single-drug regimen simplifies VTE treatment. However, the higher acquisition cost of rivaroxaban and apixaban may be a barrier for some patients.

⑥ Oral dabigatran 150 mg twice daily and oral edoxaban 60 mg once daily have each been compared with traditional therapy in randomized, double-blind, noninferiority trials involving patients with acute VTE.[55,56] In these trials, all patients were initially given at least 5 days of parenteral anticoagulation therapy (UFH or LMWH) and then randomized to study treatment. Both dabigatran and edoxaban were noninferior to warfarin following the use of a parenteral anticoagulant. Dabigatran caused similar rate of major bleeding[55] and edoxaban significantly fewer major bleeding events when compared to warfarin.[56] The requirement for parenteral anticoagulation prior to initiation of dabigatran or edoxaban therapy is a disadvantage compared with single-drug approaches to VTE treatment. DOACs are preferred over traditional anticoagulation therapy approaches for the treatment of VTE in consensus guidelines.[57,58] Edoxaban and rivaroxaban may be reasonable alternatives to LMWH monotherapy for patients with cancer-associated VTE.[47,59]

Low-Molecular-Weight Heparin

LMWH given subcutaneously in fixed, weight-based doses (enoxaparin 1 mg/kg twice daily or 1.5 mg/kg once daily) is at least as effective as UFH given intravenously for the treatment of VTE.[60] UFH is preferred as the initial anticoagulant for unstable patients in case thrombolytic therapy or embolectomy is needed.[61] Among patients without cancer treated initially with LMWH, acute treatment with LMWH is generally transitioned to long-term warfarin therapy after at least 5 days of overlap with warfarin and an INR of 2.0 or greater.

Fondaparinux

Fondaparinux is a safe and effective option for acute VTE treatment.[18] Compared with weight-based LMWH dosing, this flexible dosing scheme may be particularly useful with obese patients and those whose weight falls between commercially available prefilled LMWH syringes. Fondaparinux may be used to overlap with warfarin during initiation or for at least 5 days of parenteral anticoagulation prior to edoxaban or dabigatran initiation for acute VTE. Careful attention should be paid to renal function as fondaparinux is contraindicated if CrCl is <30 mL/min (0.5 mL/s).[62]

Unfractionated Heparin

UFH may be administered subcutaneously (SQ) or by continuous intravenous (IV) infusion (Table 38-6). The anticoagulant response to UFH is highly variable when given intravenously and it is standard practice to adjust the dose according to coagulation test results. The aPTT and antifactor Xa concentration are the two most commonly used tests to monitor the UFH anticoagulant effect. The therapeutic aPTT range at each institution should be adapted to the responsiveness of the reagent and instrument used.[60] Weight-based UFH dosing by IV infusion is preferred. However, failure to give a sufficient IV UFH dose increases VTE recurrence risk.[60] IV UFH requires hospitalization with frequent aPTT monitoring and dose adjustment. Failure to achieve an adequate response to UFH therapy is common despite close monitoring.[60] Consequently, UFH has largely been replaced by LMWH, fondaparinux, and DOACs for the management of acute VTE. However, because the clearance of LMWH, fondaparinux, and DOACs is dependent on renal function, UFH continues to have a role in acute VTE treatment in patients with CrCl <30 mL/min (0.5 mL/s).[18,63] UFH should also be used in unstable patients potentially requiring invasive interventions or thrombolytic therapy.[18,63]

TABLE 38-6

Weight-Based[a] Dosing for UFH Administered by Continuous IV Infusion for Acute VTE

Initial Bolus Dose	Initial Infusion Rate
80 units/kg (maximum = 10,000 units)	18 units/kg/hr (maximum = 2,300 units/hr)
Maintenance Infusion Rate	
Activated Partial Thromboplastin Time (seconds)	**Dose Adjustment**
<37 (or antifactor Xa <0.20 unit/mL [kU/L])	80 units/kg bolus, and then increase infusion by 4 units/kg/hr
37-47 (or antifactor Xa 0.20-0.29 unit/mL [kU/L])	40 units/kg bolus, and then increase infusion by 2 units/kg/hr
48-71 (or antifactor Xa 0.30-0.70 unit/mL [kU/L])	No change
72-93 (or antifactor Xa 0.71-1 unit/mL [kU/L])	Decrease infusion by 1-2 units/kg/hr
>93 (or antifactor Xa >1 unit/mL [kU/L])	Hold infusion for 1 hr, and then decrease by 3 units/kg/hr

[a] Use actual body weight for all calculations. Adjusted body weight may be used for obese patients (>130% of ideal body weight).

Data from Reference 60.

Warfarin

⑤ Warfarin monotherapy is unacceptable for acute VTE treatment because of the slow onset of effect. However, warfarin is effective for long-term VTE management provided it is started concurrently with rapid-acting injectable anticoagulant therapy.[58] Injectable anticoagulation should overlap with warfarin therapy for at least 5 days and until an INR ≥2 has been achieved for at least 24 hours.[58] The initial dose of warfarin should be 5 to 10 mg for most patients with subsequent adjustments to achieve and maintain an INR between 2 and 3 (Fig. 38-9).

Thrombolysis and Thrombectomy

Most VTE cases require only anticoagulation therapy. In select cases, removing the occluding thrombus by pharmacologic or surgical means may be warranted.[58] Thrombolytic agents are proteolytic enzymes that enhance the conversion of plasminogen to plasmin. Thrombolytic therapy for DVT improves early venous patency, but this does not necessarily translate into improved long-term outcomes.[58] If thrombolytic therapy is pursued, catheter-directed thrombolysis is suggested over systemic thrombolysis as the latter is not considered appropriate for DVT treatment in the United States.[58] Patients with extensive proximal DVT presenting within 14 days of symptom onset, with good functional status, low bleeding risk, and a life expectancy of a year or more are thrombolysis candidates (Table 38-7). Patients with DVT involving the iliac and common femoral veins are at the highest risk for postthrombotic syndrome and may derive the most benefit from thrombus removal strategies.

TABLE 38-7

Thrombolysis for the Treatment of VTE

- The majority of patients with VTE do not require thrombolytic therapy
- Thrombolytic therapy for DVT should be reserved for patients who present with extensive proximal DVT (eg, ileofemoral) within 14 days of symptom onset, have good functional status, and are at low risk of bleeding
- Thrombolytic therapy should be administered to patients with massive PE with evidence of hemodynamic compromise (hypotension or shock) unless contraindicated by bleeding risk
- Routine use of thrombolytic therapy is not recommended for PE without hypotension or shock but might be appropriate for selected high-risk patients (see below) provided the risk of bleeding is acceptable
- Factors associated with high risk for adverse PE outcomes include:
    - Ill-appearing patients with marked dyspnea, anxiety, and low oxygen saturation
    - Elevated troponin levels
    - Right ventricular dysfunction on echocardiography
    - Right ventricular enlargement on chest CT
- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (ie, recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke or intracranial hemorrhage)
- Baseline labs should include CBC and blood typing in case transfusion is needed
- Alteplase 100 mg infused via peripheral vein over 2 hours is the most commonly used thrombolytic for patients with PE
- Before thrombolytic therapy for PE, IV UFH should be administered in full therapeutic doses
- During thrombolytic therapy, it is acceptable to either continue or suspend IV UFH (suspending UFH is the most common practice in the United States)
- aPTT should be measured following the completion of thrombolytic therapy
    - If aPTT is <80 seconds, UFH infusion should be started and adjusted to maintain aPTT in the therapeutic range
    - If aPTT is >80 seconds, measure every 2-4 hours and start UFH infusion when aPTT is <80 seconds
- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

CBC, complete blood cell count; CT, computed tomography

Data from References 1,58.

In acute PE, successful clot dissolution with thrombolytic therapy reduces elevated pulmonary artery pressure and normalizes right ventricular dysfunction. However, the risk of death from PE should outweigh the risk of serious bleeding associated with thrombolytic therapy. Therefore, patients being considered for thrombolytic therapy should be screened carefully for contraindications relating to bleeding risk (Table 38-7).[58,64] Thrombolytic therapy is considered necessary in addition to aggressive interventions such as volume expansion, vasopressor therapy, intubation, and mechanical ventilation for patients with massive PE accompanied by shock and cardiovascular collapse (about 5% of patients with PE).[58,64] Thrombolytic therapy in these patients should be administered without delay to reduce risk of progression to multisystem organ failure and death.

The benefit of thrombolytic therapy in patients with PE without hemodynamic compromise is less clear and requires rapid risk stratification to determine the initial treatment intensity.[61] Low-risk patients can be discharged early or managed as outpatients, and high-risk patients should be admitted to an intensive care unit for surveillance and/or advanced therapies such as thrombolysis.[65] The Pulmonary Embolism Severity Index (PESI) is a prognostic tool utilizing 11 routinely available clinical parameters: demographics (age and gender), comorbid illnesses (cancer, heart failure, and chronic lung disease), and clinical findings (pulse, systolic blood pressure, respiratory rate, temperature, mental status, and arterial oxygen saturation). PESI stratifies patients into five risk classes with classes I and II considered low risk.[65] Patients with acute PE but no evidence of hemodynamic compromise, right ventricular strain by echocardiography, or elevated cardiac biomarker levels have higher mortality risk than patients without these findings, but the risk of death is much less than patients with hemodynamic compromise. Therefore, routine use of thrombolytic therapy is not recommended in these patients, but this decision needs to be individualized (Table 38-7).[58]

In rare circumstances, surgical thrombectomy for extensive ileofemoral DVT may be necessary, but catheter-directed thrombolysis is preferred if bleeding risk is acceptable.[21] For acute PE treatment, catheter-based embolectomy might be suitable in settings where the necessary expertise and resources are available for patients who have contraindications to thrombolytic therapy, have failed thrombolytic therapy, or in whom death is likely before thrombolytic onset.[21] Surgical embolectomy is reserved for patients experiencing massive PE with hemodynamic instability when thrombolysis is either contraindicated or failed, or when insufficient time exists for thrombolysis to take effect.[18] In chronic PE cases—where persistent emboli produce CTPH, hypoxemia, and right-sided heart failure—surgical pulmonary thromboendarterectomy offers greater benefit than anticoagulants and may be the treatment of choice if performed by an experienced surgical team.[21] A permanent IVC filter is usually inserted before or during the procedure and long-term anticoagulation therapy is needed.[18]

Special Populations

Some patient populations with VTE require special consideration due to increased risk for recurrence, adverse events, or altered anticoagulant pharmacokinetics.

Pregnancy

Anticoagulation therapy is commonly used for the prevention and treatment of VTE during pregnancy.[8] UFH and LMWH do not cross the placenta and are preferred during pregnancy (Table 38-8).[8] Warfarin crosses the placenta and can result in fetal bleeding, central nervous system abnormalities, and embryopathy and should not be used for VTE treatment during pregnancy.[8] Women of childbearing age taking warfarin must be counseled regarding fetal risks and the need for effective contraception. DOACs should be avoided in pregnancy until more information regarding their safety is available.[66–69] Fondaparinux has not been extensively studied in pregnancy and may cross the placenta.[62] However, fondaparinux may be considered in pregnant patients intolerant to LMWH or those with a history of HIT.[70]

TABLE 38-8

Anticoagulant Use During Pregnancy and Delivery

Acute treatment[a]	LMWH • Enoxaparin 1 mg/kg SC q 12 hr or 1.5 mg/kg q 24 hr *Or* • Dalteparin 100 units/kg SC q 12 hr *Or* UFH • Initiate using weight-based IV therapy and adjust dose to achieve therapeutic anti-Xa level for at least 5 days • Transition to SC adjusted-dose UFH administered q 8-12 hr with mid-interval anti-Xa activity adjusted to achieve an anti-Xa level of 0.3-0.7 unit/mL [kU/L][b]
Long-term treatment[c]	LMWH • Maintain initial LMWH dose regimen throughout pregnancy *Or* • Alter LMWH dose in proportion to any weight change (usually gain) *Or* UFH • Obtain anti-Xa level at the midpoint of the dosing interval and adjust UFH dose to achieve an anti-Xa level of 0.3-0.7 unit/mL (kU/L)
Issues at the time of delivery	Elective induction of labor • Discontinue UFH or LMWH 24 hr prior to induction • Initiate therapeutic doses of UFH by IV infusion and discontinue 4-6 hr prior to the expected time of delivery if the risk of recurrent VTE is deemed high Spontaneous labor • For LMWH, if there is a reasonable expectation that significant anticoagulant effect will be present at the time of delivery: (a) epidural should be avoided and (b) reversal with protamine sulfate may be considered • For UFH, monitor the aPTT and reverse with protamine sulfate if aPTT is prolonged near the time of delivery Postpartum • Commence UFH or LMWH as soon as safely possible (usually 12 hr following delivery) • Concurrently initiate warfarin therapy and discontinue UFH or LMWH when the INR is 2 or greater • Continue anticoagulants for at least 6 weeks following delivery • Warfarin can be safely used by women who are breast-feeding

[a] Twice-daily LMWH preferred during pregnancy due to increased clearance.

[b] Anti-Xa monitoring preferred as the relationship between aPTT and heparin levels differs in pregnant compared with nonpregnant patients.

[c] As pregnancy progresses the volume of distribution of LMWH changes, glomerular filtration rate increases, and most women gain weight.

SC, subcutaneously.

Data from Reference 8.

Pregnant women with a history of VTE should receive VTE prophylaxis for 6 weeks after delivery.[71] Antenatal prophylaxis may also be indicated in women with a history of multiple VTE, VTE associated with pregnancy or estrogen therapy, or known thrombophilia. Anticoagulation for acute VTE during pregnancy should continue for at least 6 weeks postpartum and a minimum total duration of 3 months.[8] Warfarin, UFH, and LMWH are safe during breastfeeding.[60,72] It is not known if DOACs are excreted in human milk and breastfeeding is not recommended.[66–69]

Pediatric Patients

VTE in pediatric patients is increasing secondary to prematurity, cancer, trauma, surgery, congenital heart disease, and systemic lupus erythematosus. Pediatric patients rarely experience unprovoked VTE, but often develop DVTs associated with indwelling central venous catheters.[73] In many cases, recommendations for anticoagulant therapy in pediatric patients are largely extrapolated from data from clinical trials in adults. However, in recent years, the available information, knowledge, and expertise in relation to appropriate diagnosis, prevention, and clinical management of VTE in neonates and children have increased dramatically.[73] When possible, a pediatric hematologist with experience treating VTE should manage pediatric patients.[74]

Anticoagulation with LMWH and warfarin remains the most frequently used approach for VTE treatment in pediatric patients. The decision between LMWH and warfarin should depend on patient values and preferences, health services resources, infrastructure and support, indication for anticoagulation, comorbidities, and other medications. The recommended target INR range, as well as the duration of therapy, is the same as for adults.[73] Frequent INR monitoring and warfarin dose adjustments are typically required. Obtaining blood for coagulation monitoring tests in pediatric patients is challenging because many have poor venous access. Using finger-stick blood samples with point-of-care INR monitors is an option in this situation. Despite the need for daily injections, LMWH is an attractive alternative for pediatric patients due to the low potential for drug-drug interactions and less frequent laboratory testing. Most experts recommend anti-Xa activity monitoring with goal antifactor Xa levels between 0.5 and 1.0 unit/mL (kU/L) 4 to 6 hours following subcutaneous injection. Warfarin should be initiated concurrently with UFH or LMWH therapy. Similar to adults, therapy should be overlapped for a minimum of 5 days and until the INR is therapeutic. Anticoagulation should be continued for up to 3 months for provoked VTE and 6 to 12 months for unprovoked VTE.[73] DOACs are attractive alternatives in pediatric patients due to oral administration and no need for routine coagulation monitoring; however, safety, effectiveness, and dosing in this population have not been established.[66–69] Thrombolysis has been used in pediatric patients, but published data are very limited—routine use is not recommended with the exception of PE associated with hemodynamic compromise.[73]

Patients with Cancer

Cancer-related VTE is associated with threefold higher rates of recurrent VTE and up to sixfold higher rates of bleeding. In addition, increased rates of recurrent VTE have been associated with warfarin-based approaches to VTE treatment in patients with active cancer.[75] Warfarin therapy in cancer patients is often complicated by drug interactions (eg, chemotherapy and antibiotics) and the need to interrupt therapy for invasive procedures. Maintaining stable INR control is also more difficult in this patient population because of nausea, anorexia, and vomiting.[18]

Long-term LMWH monotherapy (dalteparin 200 units/kg every 24 hr for 30 days, followed by 150 units every 24 hr, or enoxaparin as described above) is a preferred option for patients with cancer-associated VTE. Treatment of cancer-related VTE with LMWH monotherapy rather than traditional warfarin-based therapy decreases recurrent VTE rates without increasing bleeding risk but does not affect overall mortality.[16,18,76,77] Advantages of LMWH over warfarin for VTE treatment in cancer are expected to be greatest in those with one or more of the following: metastatic disease, treatment with aggressive chemotherapy, extensive VTE at presentation, liver dysfunction, poor or unstable nutritional status, or desire to avoid frequent blood draws for coagulation monitoring.[18]

For patients with cancer and VTE receiving LMWH, therapy should continue for 3 to 6 months after which the LMWH can be continued or warfarin or DOAC therapy substituted. Anticoagulation therapy should continue for as long as the cancer is "active" and while the patient is receiving antitumor therapy.[18] A risk-to-benefit assessment should be performed on a regular basis considering overall clinical status, bleeding risk, quality of life, and life expectancy.[18] For patients with cancer who experience a VTE recurrence despite receiving anticoagulant therapy, LMWH appears to be more effective than warfarin-based therapy in preventing further recurrences, and increasing the anticoagulant intensity may not be necessary for this situation.[75]

Edoxaban and rivaroxaban have been compared to dalteparin monotherapy for the treatment of cancer-related VTE and were as effective as dalteparin for preventing VTE recurrence but caused more bleeding.[53,54] Excess DOAC-related bleeding often occurred in the gastrointestinal tract in patients with gastrointestinal malignancy.[53] Thus, DOACs may be an important alternative to LMWH for cancer-related VTE given the limited tolerability of long-term LMWH but should be used with caution in patients with tumors involving the gastrointestinal lumen.

Patients with Renal Insufficiency

Patients with acute or chronic kidney disease often require anticoagulation for VTE prevention or treatment. With the exception of warfarin and UFH, most anticoagulants require adequate renal function for their elimination. Accumulation of drug is possible during treatment with LMWH, fondaparinux, and most DOACs.[60,72] In addition, patients with chronic kidney disease are at increased risk of bleeding, regardless of anticoagulant choice.[25]

LMWHs are renally eliminated and should be used with caution in patients with severe renal impairment.[78] Enoxaparin has specific labeling for patients with CrCl <30 mL/min (0.5 mL/s), but supporting evidence is limited to pharmacokinetic modeling analyses.[79] Bleeding and recurrent VTE outcomes for patients with CrCl <30 mL/min (0.5 mL/s) receiving enoxaparin 1mg/kg once daily for acute VTE treatment was comparable to patients with normal renal function in one retrospective study.[63] However, UFH remains preferred for acute VTE treatment in this setting until further evidence becomes available.[18] Fondaparinux is contraindicated in patients with CrCl <30 mL/min (0.5 mL/s).

DOACs are eliminated to varying[80] degrees through the kidney and require dose adjustment for renal impairment.[66–69] Periodic renal function assessment is important during long-term DOAC therapy, especially for patients with CrCl <50 mL/min (0.83 mL/s). The use of dabigatran and rivaroxaban in patients with CrCl <30 mL/min (0.5 mL/s) should be avoided.[67,68] Edoxaban dosing is reduced to 30 mg once daily in patients with CrCl 15 to 50 mL/min (0.25-0.83 mL/s).[69] Product labeling for apixaban permits its use in patients with end-stage kidney disease and emerging data suggest that apixaban may be an option for these patients.[66,80]

Patients Undergoing Invasive Procedures

Patients scheduled to undergo invasive procedures often require temporary discontinuation of anticoagulation therapy.[81] The decision to withhold anticoagulation therapy should be based on the bleeding risk associated with the procedure and the patient’s underlying thromboembolic risk. Anticoagulation therapy is typically continued in patients undergoing minimally invasive procedures such as dental work, cataract surgery, or minor dermatologic procedures.[82] If the bleeding risk from the procedure is considerable, near-normal hemostasis should be achieved prior to the procedure. For DOACs the time required for the restoration of normal hemostasis after interrupting therapy is dependent on renal function and medication half-life. Stopping DOACs 2 days prior to invasive procedures is usually sufficient to restore near-normal hemostasis for patients with normal renal function. Additional days off therapy may be required for patients with impaired renal function.[66–69] The anticoagulant effect of dabigatran can be rapidly reversed with idarucizumab and andexanet can be used to reverse the effect of rivaroxaban and apixaban for patients requiring urgent surgical interventions.[83,84] Up to 5 days may be required for the restoration of normal hemostasis after warfarin discontinuation. Patients at high thromboembolic risk (ie, DVT or PE in the previous month) may be considered for so-called “bridge therapy” with UFH or an LMWH given before and after the procedure.[82] Bridge therapy has been associated with increased major bleeding without offering additional recurrent VTE risk reduction in low-to-moderate risk patients. Therefore, most patients with VTE can safely interrupt warfarin for invasive procedures without using bridge therapy.[81] Resumption of anticoagulation following an invasive procedure is based on post-procedure bleeding risk and drug-specific time to onset of the anticoagulant effect (Table 38-9).

TABLE 38-9

Anticoagulant Interruption and Resumption around High Bleeding-Risk Invasive Procedures

Anticoagulant	Timing of Anticoagulant Interruption Prior to Procedure	Day of Procedure	Timing of Anticoagulant Resumption After Procedure[a]
UFH	• IV: hold infusion 6-8 hours prior to the procedure • SC: last dose 12 hours prior to the procedure	No anticoagulation	24-48 hours after the procedure
LMWH	Last dose 24 hours prior to the procedure		
Fondaparinux	Last dose 2 days prior to the procedure		
Apixaban	Last dose 2 days prior to the procedure		
Dabigatran • CrCl < 50 mL/min (0.83 mL/s) • CrCl ≥ 50 mL/min (0.83 mL/s)	• Last dose 3-4 days prior to the procedure • Last dose 2 days prior to the procedure		
Edoxaban	Last dose 2 days prior to the procedure		
Rivaroxaban	Last dose 2 days prior to the procedure		
Warfarin	Last dose 4-5 days prior to the procedure		Day of or 1 day after the procedure

[a] Assumes hemostasis has been achieved.

[b] Warfarin hold time is dependent on the INR prior to beginning the interruption and the target INR for the day of the procedure (eg, patients beginning with elevated INR may require a longer holding period to achieve target INR for the day of procedure)

DRUG CLASS INFORMATION

⑨ Optimal use of anticoagulant therapies requires knowledge of pharmacologic and pharmacokinetic characteristics as well as systematic management and ongoing patient education (Table 38-5) to reduce the risks of bleeding and therapeutic failure (Table 38-10).

TABLE 38-10

Risk Factors for Major Bleeding While Taking Anticoagulation Therapy

Higher anticoagulation intensity
Initiation of therapy (first few days and weeks)
Unstable anticoagulation response
Age >65 years
Concurrent aspirin or other antiplatelet therapy
Concurrent nonsteroidal anti-inflammatory drug use
History of gastrointestinal tract bleeding
Recent surgery or trauma
High risk for fall/trauma
Heavy alcohol use
Renal failure
Cerebrovascular disease
Malignancy

Data from Reference 25.

Direct Oral Anticoagulants

Shortcomings with warfarin, LMWH, fondaparinux, and UFH have driven the search for replacements with rapid anticoagulant onset and oral administration without the need for monitoring. The DOACs have provided a major advance in VTE prevention and treatment.

Pharmacology/Mechanism of Action

Rivaroxaban, apixaban, and edoxaban are potent and selective inhibitors of both free and clot-bound factor Xa that do not require antithrombin to exert their anticoagulant effect.[58] Dabigatran is a selective, reversible, direct factor IIa (thrombin) inhibitor.[67]

Pharmacokinetics

Rivaroxaban, apixaban, and edoxaban have good oral bioavailability (greater than 60%), whereas dabigatran is formulated as a prodrug (dabigatran etexilate) to overcome poor oral bioavailability.[66-69] All DOACs reach peak plasma concentrations in less than 4 hours. Each drug is renally eliminated to a variable extent, as low as 27% for apixaban and as high as 80% for dabigatran.[66-69] Terminal half-lives range from 9 to 12 hours for rivaroxaban, apixaban, and edoxaban, and 14 to 17 hours for dabigatran.[66-69] DOACs should be used with caution in patients with renal dysfunction.[85] Rivaroxaban and apixaban are substrates of cytochrome p450 (CYP) 3A4 and the P-glycoprotein (P-gp) transporter.[66] Edoxaban and dabigatran do not undergo significant CYP 3A4 metabolism, but all are P-gp substrates. Strong inhibitors and inducers of CYP 3A4 enzymes or P-gp may cause changes in DOAC exposure and increase the risk of bleeding or VTE events.[66-69]

Efficacy

DOACs are noninferior to warfarin therapy overlapped with LMWH for VTE treatment.[66–69] For patients who are at high risk of VTE recurrence who require extended anticoagulant therapy beyond 6 months, rivaroxaban and apixaban at either the treatment or prophylactic doses were superior to low-dose aspirin or placebo, respectively.[86,87] Similarly, when compared to LMWH, rivaroxaban and apixaban are noninferior for preventing VTE following hip or knee replacement surgery.[66–68,88]

Adverse Drug Reactions

The most common adverse drug reaction associated with DOAC therapy is bleeding.[66–69] The International Society for Thrombosis and Haemostasis defines major bleeding as fatal bleeding, any bleeding into a critical anatomic space (eg, intracranial bleeding, hemarthrosis, pericardial bleeding, or intraocular bleeding), bleeding that requires transfusion of two or more units of whole blood or red cells, or bleeding that leads to a greater than 2 g/dL (20 g/L; 1.24 mmol/L) drop in hemoglobin concentration. Bleeding that does not meet the major bleeding criteria but requires medical intervention or alteration of therapy is sometimes termed clinically relevant nonmajor bleeding. All other bleeding is considered minor and is common during anticoagulation therapy even in the most expertly managed patients. The most frequent nonbleeding adverse events in clinical trials of DOACs were gastrointestinal complaints.[66–69]

Patients presenting with significant bleeding during DOAC therapy should receive routine supportive care (fluid resuscitation, blood transfusion, maintenance of renal function, bleeding source identification, and surgical intervention if needed), and discontinuation of anticoagulation therapy.[89] Because DOACs have relatively short half-lives, these measures may control bleeding in many patients, especially those with normal renal function.[89] Activated charcoal may provide some benefit if drug intake occurred within the previous 2 hours.[89]

Idarucizumab is a humanized monoclonal antibody fragment that rapidly reverses dabigatran's anticoagulant effect following IV administration.[83] Idarucizumab can be used during emergency situations such as life-threatening bleeding and when there is a need for urgent surgical intervention. Andexanet is a recombinant Factor Xa molecule that binds the Factor Xa inhibitors rivaroxaban and apixaban without having intrinsic antithrombotic activity. It can be used for the reversal of life-threatening bleeding in patients taking rivaroxaban or apixaban (Table 38-11). If traditional hemostatic measures fail or drug-specific reversal agents are not available in a life-threatening bleeding situation, it may be reasonable to consider the use of 4-factor prothrombin complex concentrates (PCCs) while weighing the associated risk for thrombotic events. Animal, in vitro, and healthy volunteer studies have shown that these agents reverse coagulation laboratory parameters, but controlled studies of these agents in bleeding patients taking DOACs are not available. Fresh-frozen plasma (FFP) is unlikely to provide clinical benefit.[89]

TABLE 38-11

Reversal Agents for the DOACs

Reversal Agent	Target	Outcomes and Current Status
Idarucizumab (monoclonal antibody fragment)	Dabigatran	• Reversed anticoagulant effect of dabigatran in patients with serious bleeding or needing urgent reversal for a procedure • Approved by the FDA in October 2015
Andexanet (modified recombinant Factor Xa)	Rivaroxaban, Apixaban	• Reversed anticoagulant effect of rivaroxaban and apixaban in patients with intracranial hemorrhage • Approved by the FDA in May 2018

Data from References 83,90-92.

Drug-Drug and Drug-Food Interactions

Adding aspirin to DOAC therapy nearly doubles bleeding rates and should be avoided in most patients with VTE. Although the DOACs have far fewer drug interactions than warfarin, all DOACs are P-gp substrates and subject to changes in anticoagulant effect when coadministered with strong P-gp inhibitors or inducers. Rivaroxaban and apixaban are subject to interactions involving inhibitors or inducers of CYP 3A4.[66–69] Which drug interactions must be avoided is a matter of debate. Strong inducers of P-gp and CYP 3A4 enzymes such as carbamazepine and rifampin should be avoided. Caution should be used with concurrent use of strong P-gp or combination P-gp/CYP 3A4 inhibitors with a DOAC, particularly in the setting of renal insufficiency.[66–69] When interacting drugs cannot be avoided it may be best to switch to warfarin for dose adjustment guided by INR monitoring.

Dosing and Administration

Rivaroxaban and apixaban can be used in a single-drug approach for acute VTE treatment, whereas at least 5 days of parenteral anticoagulant therapy is required prior to initiating edoxaban or dabigatran for acute VTE (Fig. 38-11). The 15- and 20-mg doses of rivaroxaban should be taken with food to enhance oral absorption, but all other DOACs can be taken irrespective of food.[66–69]

Low-Molecular-Weight Heparin

LMWH fragments produced by either chemical or enzymatic depolymerization of UFHare heterogeneous mixtures of sulfated glycosaminoglycans with approximately one-third the mean molecular weight of UFH.[60] Advantages of LMWH over UFH include predictable anticoagulation dose-response, improved subcutaneous bioavailability, dose-independent clearance, longer biologic half-life, lower incidence of thrombocytopenia, and reduced need for routine laboratory monitoring.[60]

Pharmacology/Mechanism of Action

LMWH prevents thrombus growth and propagation by enhancing and accelerating the activity of antithrombin.[60] The anticoagulant effect of LMWH (and UFH) is mediated through a specific pentasaccharide sequence that binds to antithrombin, provoking a conformational change (Fig. 38-12). To inactivate thrombin, the heparin molecule must form a ternary complex bridging between antithrombin and thrombin.[60] Only molecules containing more than 18 saccharides are able to bind to both antithrombin and thrombin simultaneously. Smaller heparin molecules cannot facilitate the interaction between antithrombin and thrombin. In contrast, the inactivation of factor Xa does not require the formation of a bridge with antithrombin but requires only heparin binding to antithrombin via the specific pentasaccharide sequence. Heparin molecules with as few as five saccharide units are able to catalyze the inhibition of factor Xa. The principal difference in the pharmacologic activity of LMWH and UFH is their relative inhibition of factor Xa and thrombin. Because of smaller chain lengths, LMWH has limited activity against thrombin (Fig. 38-12). The ratio of antifactor Xa:IIa activity varies between 4:1 and 2:1.

Pharmacokinetics

Compared with UFH, LMWH has a more predictable anticoagulation response. The improved pharmacokinetic profile of LMWH is the result of reduced binding to proteins and cells.[60] The bioavailability of LMWH is about 90% when administered subcutaneously. The peak anticoagulation effect is seen within 3 to 5 hours of subcutaneous LMWH injection and the predominant mode of elimination for LMWH is renal. Consequently, the biologic half-life may be prolonged in patients with renal impairment.[60] The plasma half-life of LMWH preparations is 3 to 6 hours. Unlike UFH, the clearance of LMWH is independent of dose.[60]

Efficacy

The efficacy of LMWH for the prevention of VTE was established in clinical trials in comparison to low-dose UFH and placebo. For the treatment of VTE, the efficacy of fixed weight-based LMWH was compared to aPTT-adjusted IV UFH; all patients were transitioned to warfarin for long-term therapy.[79,93]

Adverse Drug Reactions

As with other anticoagulants, bleeding is the most common LMWH adverse drug reaction.[25] The frequency of major bleeding may be less with LMWH than with UFH, but this has not been consistently demonstrated in clinical trials.[25] Although there is no proven method for reversing LMWH anticoagulation if major bleeding occurs, IV protamine sulfate can be administered. However, because of limited binding to the shorter LMWH chains, protamine sulfate neutralizes only around 60% to 75% of LMWH anticoagulant activity.[60] The recommended dose of protamine sulfate is 1 mg/1 mg of enoxaparin or 1 mg/100 antifactor Xa units of dalteparin administered in the previous 8 hours. A second protamine sulfate dose of 0.5 mg/1 mg or 100 antifactor Xa units can be given if bleeding continues. Smaller doses of protamine sulfate can be used if the LMWH dose was given in the previous 8 to 12 hours. The use of protamine sulfate is not recommended if LMWH was administered more than 12 hours earlier.[60]

Although thrombocytopenia can occur with LMWH use, the incidence of HIT is one-third of that observed with UFH, perhaps due to the reduced propensity of LMWH to bind to platelets.[60] However, LMWH exhibits nearly 100% cross-reactivity with UFH antibodies in vitro, and thus LHWH should be avoided in patients with an established diagnosis or history of HIT.[60] The risk of osteoporosis appears to be lower with LMWH than with UFH.[60]

Drug-Drug Interactions

The concurrent use of drugs that enhance bleeding risk should be avoided during LMWH therapy if possible. This includes aspirin or other antiplatelet agents, nonsteroidal anti-inflammatory drugs, dipyridamole, or sulfinpyrazone.[79,93]

Dosing and Administration

LMWH is given in fixed or weight-based doses based on the product and indication. Dosesshould be based on actual body weight and dose capping (ie, a fixed, maximum daily dose) is not recommended.[78] The dose for enoxaparin is expressed in milligrams, whereas dalteparin doses are expressed in units of antifactor Xa activity. LMWH is given by subcutaneous injection.

Significant LMWH accumulation is possible in patients with severe renal impairment.[60] The enoxaparin dose should be reduced or the dosing interval extended to once daily in patients with CrCl <30 mL/min (0.5 mL/s).[79] Dalteparin is less reliant upon renal elimination than enoxaparin; however, its pharmacokinetics are insufficiently characterized in renal insufficiency.[94] LMWH use in patients with end-stage renal disease receiving hemodialysis is poorly understood; thus, UFH is preferred for these patients.[60] Some experts recommend measuring antifactor Xa activity if LMWH therapy is continued for more than a few days in patients with severe renal disease.[60] For patients with CrCl <30 mL/min (0.5 mL/s) who require VTE prophylaxis, enoxaparin 30 mg once daily is recommended.[60]

Fondaparinux

Fondaparinux is a synthetic molecule consisting of the five critical saccharide units that bind specifically, but reversibly, to antithrombin. Unlike UFH or LMWH, fondaparinux inhibits only factor Xa activity.[60]

Pharmacology/Mechanism of Action

Fondaparinux prevents thrombus generation and clot formation by indirectly inhibiting factor Xa activity through its interaction with antithrombin (Fig. 38-12). Fondaparinux is not destroyed during this process and is released to bind to other antithrombin molecules.[60]

Pharmacokinetics

Fondaparinux is rapidly and completely absorbed following subcutaneous administration achieving peak plasma concentrations approximately 2 hours after a single dose and 3 hours with repeated once-daily dosing. At therapeutic concentrations, fondaparinux does not bind to red blood cells or other plasma proteins.[60] Fondaparinux is primarily eliminated unchanged in the urine and its terminal elimination half-life is 17 to 21 hours.[60] The anticoagulant effect of fondaparinux persists for 2 to 4 days following discontinuation of the drug in patients with normal renal function.

Efficacy

The efficacy of fondaparinux for the prevention of VTE was established in several clinical trials in comparison to LMWH. For the treatment of VTE, the efficacy of fixed weight-based dosing of fondaparinux was compared to weight-based dosing of LMWH; all patients were transitioned to warfarin for long-term therapy.[62]

Adverse Drug Reactions

The primary adverse drug reaction associated with fondaparinux therapy is bleeding.[62] Fondaparinux should be used with extreme caution with neuraxial anesthesia or following spinal puncture because of the risk for spinal or epidural hematoma formation.[62] Some case reports have implicated fondaparinux as a cause of HIT, while others have documented successful HIT treatment with fondaparinux.[95] A specific antidote to reverse the antithrombotic activity of fondaparinux is not currently available.[60]

Drug-Drug Interactions

Fondaparinux has no known pharmacokinetic drug interactions; other drugs with anticoagulant, fibrinolytic, or antiplatelet activity increase the risk of bleeding.[62]

Dosing and Administration

The dose of fondaparinux for VTE prevention is 2.5 mg injected subcutaneously once daily following surgery if hemostasis has been established. It is important to avoid initiating fondaparinux too soon because there is a significant relationship between first dose timing and major bleeding risk.[60]

Patients weighing less than 50 kg should not receive VTE prophylaxis with fondaparinux.[62] The usual duration of prophylaxis is 5 to 9 days, but extended prophylaxis for up to 35 days following a lower extremity orthopedic procedure may be used.[37] For the treatment of DVT or PE, the dose of fondaparinux is 5 mg for patients up to 50 kg, 7.5 mg for 50 to 100 kg, and 10 mg for >100 kg.[62]

Unfractionated Heparin

UFH has been used for VTE prevention and treatment for decades. Commercially available UFH preparations are derived from bovine lung or porcine intestinal mucosa. Although some differences exist between the two sources, no differences in antithrombotic activity have been demonstrated.[60]

Pharmacology/Mechanism of Action

UFH is a heterogeneous mixture of sulfated mucopolysaccharides of variable lengths and pharmacologic properties.[60]

Only one-third of the UFH molecules possess the unique pentasaccharide sequence with an affinity for antithrombin. Antithrombin inhibits factor IXa, Xa, XIIa, and IIa activity. Thrombin and Xa are most sensitive to UFH–antithrombin complex inhibition. UFH has an antifactor Xa:IIa activity ratio of 1:1 (Fig. 38-12).[60] UFH prevents thrombus growth and propagation allowing endogenous thrombolytic systems to lyse the clot.[60]

After it has produced its effect UFH uncouples from antithrombin and quickly recouples with another antithrombin molecule.[60]

Pharmacokinetics

UFH is not reliably orally absorbed because of its large molecular size and anionic structure. The bioavailability and biologic activity of UFH are limited by a propensity to bind plasma proteins, platelet factor-4, macrophages, fibrinogen, lipoproteins, and endothelial cells. This may explain the substantial interpatient and intrapatient variability observed in the anticoagulation response to UFH.[60]

The onset of anticoagulant effect after subcutaneous injection is 1 to 2 hours, peaking at 3 hours.[60] Continuous infusion is preferred for IV UFH administration.[18] Intramuscular administration is discouraged because of the risk of large hematoma formation.

UFH has a dose-dependent half-life of approximately 30 to 90 minutes.[60] There are two primary mechanisms for UFH elimination, a rapid, but saturable zero-order process involving enzymatic inactivation of heparin molecules bound to endothelial cells and macrophages, and renal elimination via a slower, nonsaturable first-order process. With typical therapeutic UFH regimens, the zero-order process predominates.[60]

Efficacy

UFH has demonstrated clinical effectiveness for the prevention and treatment of VTE over many years of clinical use.

Adverse Drug Reactions

Low-dose subcutaneous UFH is associated with a minimal risk of major bleeding. Bleeding rates for patients receiving therapeutic UFH doses range from 0% to 2%.[25] Close monitoring for bleeding signs and symptoms during UFH therapy is crucial.[25,60] When major bleeding occurs, UFH should be discontinued and the underlying bleeding source should be identified and treated. Protamine sulfate in a dose of 1 mg per 100 units of UFH (maximum of 50 mg) can be administered via slow IV infusion to reverse the anticoagulant effects of UFH.[60] Protamine sulfate neutralizes UFH in 5 minutes and persists for 2 hours. Multiple doses or prolonged infusion of protamine sulfate may be necessary if bleeding continues.[60]

HIT is a rare drug-induced immunologic reaction requiring immediate intervention.[96] The most common complication of HIT is VTE; arterial thromboembolic events occur less frequently. Approximately 5% to 10% of patients with HIT die, usually from thrombotic complications.[96] Thrombocytopenia (defined as a platelet count <150 × 10^3/mm^3 [150 × 10^9/L]) is the most common clinical HIT manifestation. HIT should be suspected if platelet counts decrease by 30% to 50% but remain above 150 × 10^3/mm^3 (150 × 10^9/L).[96] The characteristic onset of falling platelet count occurs in the first 5 to 10 days after initiation of UFH (Day 0 being the first day of UFH), particularly when administered perioperatively.[96] Thrombocytopenia alone is not sufficient for diagnosing HIT; serologic confirmation of heparin antibodies using an assay available only in a few specialty laboratories is required.[96] Falsely diagnosing HIT can have serious consequences including unnecessary anxiety, unnecessary UFH withdrawal, and the use of alternative anticoagulants with higher bleeding risk. The use of a clinical prediction rule, such as the 4Ts score (thrombocytopenia, timing of platelet count fall or thrombosis, thrombosis, other explanations for thrombocytopenia) can improve the predictive value of platelet count monitoring and heparin antibody testing.[96,97] A 4Ts score should be calculated when HIT is suspected in patients receiving heparin (UFH or LMWH). If the 4Ts score is low (3 or less), no further workup is needed, whereas a moderate (4 to 5) or high (6 to 8) 4Ts score requires further HIT workup including serologic testing.[98] In the setting of new thrombosis occurring in conjunction with falling platelets and a moderate or high 4Ts score, all sources of heparin should be discontinued. Alternative anticoagulation with a direct thrombin inhibitor or fondaparinux should then be initiated. If warfarin therapy is being used, it should be discontinued and reversed with vitamin K. Once platelet counts have recovered, warfarin can be resumed so long as it is overlapped with a direct thrombin inhibitor or fondaparinux until the INR is ≥2.0.[96]

Using UFH in doses ≥20,000 units/day for more than 6 months, especially during pregnancy, is associated with significant bone loss and may lead to osteoporosis.[60]

Drug-Drug and Drug-Food Interactions

Few drug interactions are reported with UFH, but concurrent use with other anticoagulants, thrombolytics, and antiplatelet agents increases bleeding risk.[60]

Dosing and Administration

UFH dose is expressed in units of activity. For VTE prevention, UFH is given by subcutaneous injection in the abdominal fat layer. The typical prophylaxis dose is 5,000 units every 8 to 12 hours. When immediate and full anticoagulation is required, an IV bolus dose followed by a continuous infusion is preferred (Table 38-6).[60] Subcutaneous UFH (initial dose of 333 units/kg followed by 250 units/kg every 12 hours) also provides adequate therapeutic anticoagulation for the treatment of acute VTE and does not require aPTT or anti-Xa monitoring.[60]

Warfarin

Because of its narrow therapeutic index, predisposition to drug and food interactions, and propensity to exacerbate bleeding, warfarin requires frequent monitoring and extensive patient education to achieve optimal outcomes.[72]

Pharmacology/Mechanism of Action

Warfarin exerts its anticoagulation effect by inhibiting the enzymes responsible for the cyclic vitamin K interconversion in the liver.[72] Vitamin K in its reduced form is a required cofactor for vitamin K-dependent carboxylation of factors II, VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. Hepatic carboxylation of the N-terminal region of these proteins is required for biologic activity. By inhibiting the reduced vitamin K supply used in the production of these proteins, warfarin therapy produces partially carboxylated and decarboxylated coagulation proteins with reduced activity.[72] Warfarin has no direct effect on previously circulating clotting factors or previously formed thrombus. The time required for warfarin to achieve its pharmacologic effect is dependent on coagulation protein elimination half-lives (6 hours for factor VII and 72 hours for prothrombin).[72] Full antithrombotic effect is not achieved for at least 6 days after warfarin therapy initiation. By suppressing fully functional clotting factor production, warfarin prevents initial thrombus formation and propagation.[72]

Pharmacokinetics

Warfarin is a racemic mixture of *R* and *S* isomers, with *S*-warfarin being 2.7 to 3.8 times more potent than *R*-warfarin.[72] Warfarin is rapidly and extensively absorbed from the gastrointestinal tract (bioavailability >90%) and reaches peak plasma concentration within 4 hours of oral administration. Warfarin is 99% bound to plasma proteins and undergoes stereoselective metabolism via CYP 1A2, 2C9, 2C19, 2C8, 2C18, and 3A4 isoenzymes in the liver, with 2C9 being the main enzyme to modulate the elimination of *S*-warfarin.[99] Warfarin pharmacokinetics varies substantially between individuals leading to large interpatient differences in dose requirements. Genetic variations in the 2C9 isoenzyme and vitamin K epoxide reductase (VKOR) have been shown to correlate with warfarin dose requirements.[72] Given the greater potency of *S*-warfarin, coadministration of drugs that induce or inhibit the CYP 2C9 isoenzyme is more likely to cause clinically significant interactions.[72]

Efficacy

Warfarin has demonstrated clinical effectiveness for the prevention and treatment of VTE over many years of clinical use.

Adverse drug reactions

Warfarin's primary adverse drug reaction is bleeding that can range from mild to life-threatening.[72] Although warfarin does not cause bleeding per se, it exacerbates bleeding from existing lesions and can enable massive bleeding from ordinarily minor sources.[72] Anticoagulation therapy intensity is an important bleeding risk factor; the likelihood of bleeding rises with increasing INR values.[72] Therefore, maintaining the INR within the target range is important to reduce bleeding risk. Most patients with asymptomatic INR elevations between 4.5 and 10 can be safely managed by withholding warfarin alone.[5] For an INR >10 without evidence of bleeding, oral vitamin K 2.5 mg is recommended but does not improve clinical outcomes compared to withholding warfarin alone.[100] Vitamin K can be administered subcutaneously, IV, or orally; the oral route is preferred in the absence of serious bleeding. Vitamin K should be used cautiously in patients at high thromboembolism risk due to the possibility of INR overcorrection. Conversely, simply withholding warfarin therapy may not lower high INRs quickly enough in patients at high bleeding risk or in situations associated with prolonged INR elevations such as drug interactions and intentional overdoses.

Patients with warfarin-associated life-threatening bleeding require supportive care and rapid reversal of anticoagulation with both 4-factor PCC (rather than FFP) and 5 to 10 mg of vitamin K (administered via slow IV injection).[5]

Other adverse drug reactions associated with warfarin are uncommon but can be serious.[72] The etiology of the "purple toe syndrome" is unknown, but is thought to be the result of cholesterol microembolization into the arterial circulation of the toes.[72] If recognized early, complete resolution can be achieved by simply substituting a difference anticoagulant for warfarin.[101] Warfarin-induced skin necrosis is a serious dermatologic reaction usually manifesting in the first week of therapy as a painful maculopapular rash and ecchymosis or purpura that subsequently progresses to necrotic gangrene. Areas of the body rich in subcutaneous fat, such as the breasts, thighs, buttocks, and abdomen are most commonly affected.[72] If skin necrosis is suspected, warfarin therapy should be discontinued immediately, reversed with vitamin K and either FFP or PCC, and full-dose UFH or LMWH therapy initiated. Patients with a history of skin necrosis should restart warfarin with extreme caution, if at all, using small doses and gradual titration under full-dose unfractionated heparin or LMWH coverage until a therapeutic INR is achieved.[72]

Drug-Food and Drug-Drug Interactions

The pharmacokinetic and pharmacodynamic properties of warfarin predispose patients to numerous clinically important food and drug interactions.[102] Vitamin K can reverse warfarin's pharmacologic activity; many foods contain sufficient vitamin K to reduce the anticoagulation effect if consumed in large portions or repetitively within a short period of time.[72] Patients should be instructed to maintain a relatively consistent intake of vitamin K–rich foods (Table 38-12). It is important to stress consistency rather than abstinence.

TABLE 38-12

Vitamin K Content of Select Foods[a]

Very High (>200 mcg)	High (100-200 mcg)	Medium (50-100 mcg)	Low (<50 mcg)
Brussel sprouts	Basil	Apple, green	Apple, red
Chickpeas	Broccoli	Asparagus	Avocado
Collard greens	Chive	Cabbage	Beans
Coriander	Coleslaw	Cauliflower	Breads, grains
Endive	Cucumber (with peel)	Mayonnaise	Carrot
Kale	Canola oil	Nuts, pistachio	Cereal
Lettuce, red leaf	Green onion/scallion	Squash, summer	Celery
Parsley	Lettuce, butterhead		Coffee
Spinach	Mustard greens		Corn
Swiss chard	Soybean oil		Cucumber (without peel)
Tea, green			Dairy products
Tea, black			Eggs
Turnip greens			Fruit (varies)
Watercress			Lettuce, iceberg
			Meats, fish, poultry
			Pasta
			Peanuts
			Peas
			Potato
			Rice
			Tomato

[a] Approximate amount of vitamin K per 100 g (3.5 oz) serving.

Data from Reference 24.

Pharmacokinetic drug interactions with warfarin primarily result from alterations in hepatic metabolism. Drugs inhibiting or inducing CYP 2C9, 1A2, and 3A4 isoenzymes have the greatest potential to significantly alter warfarin therapy response.[72] Drugs altering hemostasis or platelet function (eg, aspirin, clopidogrel) can increase bleeding risk without altering warfarin pharmacokinetics or impacting the INR.[72] Clinicians should advise patients on warfarin to report potential interactions to their anticoagulation provider whenever a drug product, dietary supplement, or herbal product is initiated or stopped, whether prescribed or available over the counter. If there is a known drug interaction or doubt about the potential to alter the warfarin response, more frequent INR testing is recommended with warfarin dose adjustments as needed to maintain INRs in the target range.[102]

Dosing and Administration

The dose of warfarin is individualized based on the desired target INR range and anticoagulant response by periodically measuring the PT and calculating the INR.[72] The pharmacodynamic response and pharmacokinetic disposition of warfarin between and within patients are highly variable. Therefore, the dose of warfarin must be individualized based on frequent clinical and laboratory monitoring.[72] The average weekly warfarin dose is between 25 and 55 mg. Some patients require lower than usual dose requirements, including patients who are of advanced age (>65 years), have an elevated baseline INR, poor nutritional status, liver disease, genetic polymorphisms in CYP 2C9 and VKOR, and concurrent use of medications known to enhance the effect of warfarin.[72] Higher than usual dose requirements are also necessary in some patients, including concurrent use of medications known to induce the metabolism of warfarin such as rifampin and carbamazepine, high dietary vitamin K intake, and genetic polymorphisms in CYP 2C9. It is important to collect a complete medication history, including the use of herbal and nutritional products as these can influence warfarin's metabolism, dose requirements, and the risk of bleeding.[72]

Initiating warfarin therapy with 5 to 10 mg daily and adjusting the dose based on the INR response will produce therapeutic INRs in 5 to 7 days for most patients (Fig. 38-9). Lower starting doses may be acceptable based on patient-related factors such as advanced age, malnutrition, liver disease, or heart failure. Starting doses >10 mg should be avoided.[72] When warfarin therapy is initiated in the outpatient setting, the INR should be measured every 3 to 4 days until stabilized. For patients with acute VTE, a parenteral, rapid-acting anticoagulant such as UFH, LMWH, or fondaparinux should be overlapped with warfarin therapy for at least 5 days regardless of whether the target INR has been achieved earlier.[18,72]

It is important to allow sufficient time for changes in the INR to occur when adjusting warfarin doses. In general, maintenance dose changes should not be made more frequently than every 3 days. When adjusting maintenance warfarin doses, the weekly dosage should be reduced or increased by 5% to 25%; the full effect of dose changes may not become evident for 5 to 7 days or longer.[72] Patients demonstrating a stable response to warfarin as evidenced by consistently therapeutic INR results on the same warfarin dose can have INRs checked as infrequently as every 8 to 12 weeks, although most stable patients are tested approximately every 4 to 6 weeks.[5]

Therapeutic Considerations

Prevention Versus Treatment of Venous Thromboembolism

Lower doses of LMWH and DOACs are used for VTE prevention than during VTE treatment. Warfarin may be targeted to a traditional INR range (2.0 to 3.0) or reduced-intensity (1.5 to 2.5) for VTE prophylaxis. Orthopedic surgeons frequently prefer the lower INR range due to perceived lower bleeding risk. VTE prophylaxis in high-risk hospitalized patients is typically discontinued at discharge. In contrast, after certain surgeries (eg, major orthopedic surgery), VTE prophylaxis continues following hospital discharge for up to 35 days.

VTE treatment requires full therapeutic anticoagulant doses for at least 3 months. Patients unwilling to self-administer LMWH or fondaparinux injections may prefer apixaban or rivaroxaban. The duration of anticoagulant therapy after acute VTE is principally determined by whether the clot was provoked, unprovoked, or recurrent. Three months of therapeutic anticoagulation is sufficient following a first episode of VTE provoked by major transient risk factors such as surgery, pregnancy, or trauma. Most patients with unprovoked or recurrent VTE should receive long-term anticoagulation for secondary VTE prevention. Patients selected for long-term secondary anticoagulation traditionally receive standard therapeutic doses. In patients for whom there is clinical equipoise regarding anticoagulation continuation, prophylactic doses of apixaban and rivaroxaban are as effective as full therapeutic doses after 6 months of treatment has been completed.[86,87] However, prophylactic doses were not safer than therapeutic doses as the risk of major bleeding was low for both options. Switching to aspirin for long-term secondary VTE prevention is also an option but is less effective than continuing anticoagulation therapy.[103,104]

Weight

Patients at extremes of body weight were underrepresented in DOAC VTE treatment trials. There is speculation regarding whether very obese or very small patients receive equivalent anticoagulant effects with DOAC when compared to other patients. The International Society of Thrombosis and Haemostasis suggests that standard doses of rivaroxaban or apixaban, without monitoring of peak and trough concentrations, are among the appropriate anticoagulant options for VTE treatment or prevention regardless of high BMI and weight.[105] They suggest avoiding dabigatran and edoxaban for VTE treatment and prevention in patients with BMI >40 kg/m^2 or weight >120 kg, given that data are either unconvincing (dabigatran) or lacking (edoxaban). DOACs should be avoided for both prevention and treatment of VTE in the acute setting following bariatric surgery because of concerns of decreased absorption.[105] Switching to a DOAC after at least 4 weeks following surgery may be reasonable but obtaining a DOAC trough level to check for drug absorption and bioavailability is suggested (see Evaluation of Therapeutic Outcomes section).[105]

LMWH dosing in obesity frequently causes concern. Patients weighing more than 90 kg would exceed the maximum dose specified in the approved labeling for dalteparin (18,000 units).[93] However, evidence supports similar anti-Xa exposure to LMWH and no increase in bleeding risk compared to nonobese patients when doses based on actual body weight without capping are administered.[106] Fondaparinux is a convenient option for obese patients as the 10 mg dose is suitable for acute VTE treatment in patients >100 kg.[62] Obese patients requiring VTE prophylaxis may need higher than normal LMWH doses. For example, enoxaparin 40 mg subcutaneously twice daily may be more effective than usual VTE prophylaxis doses for patients undergoing bariatric surgery.[107]

Response to Previous Therapy

Other than bleeding, anticoagulants are generally well tolerated. However, adverse reactions, treatment failure, or allergies during previous therapy may necessitate preferential use of one anticoagulant over another.

Warfarin allergy is rare and often related to dyes or tablet excipients rather than the active ingredient. Warfarin 10 mg tablets contain no dye and can be considered when an allergy is suspected. Patients experiencing dabigatran-related dyspepsia can try taking the dose with a full glass of water or food. Transitioning to another DOAC or warfarin may be necessary.

Cost is an important aspect of personalizing anticoagulant therapy for VTE prevention and treatment. For patients unable to afford DOACs, warfarin remains a cost-effective option.

Patients suspected of having a recurrent VTE during anticoagulant therapy should have their adherence to therapy assessed and imaging compared to historical data to ensure the clot is new. Determining and correcting the causes of poor medication adherence to anticoagulation therapy should occur before switching anticoagulants. Malignancy should be considered when anticoagulant adherence is verified. Switching to an LMWH is recommended for breakthrough VTE occurring during oral anticoagulation therapy.[21] Patients having breakthrough VTE during LMWH should be switched to twice daily injections (if receiving once-daily LMWH) and considered for dose escalation of 25% to 33%.[21] Switching to an oral factor Xa inhibitor may also be an option given the comparable efficacy of edoxaban and dalteparin for the treatment of cancer-related VTE; however, less is known regarding their use in breakthrough VTE.

Pharmacogenomics

CYP2C9 is the hepatic microsomal enzyme responsible for the metabolism of the more potent S-enantiomer of warfarin. Polymorphisms in CYP 2C9 and the gene coding for VKOR (known as vitamin K epoxide reductase complex 1) explain a substantial proportion of warfarin dose variability between patients. Dosing algorithms using CYP 2C9 and VKOR pharmacogenomics, as well as clinical and drug interaction information, have been developed to assist providers more accurately select initial warfarin doses based upon a predicted maintenance warfarin dose for an individual patient (see www.warfarindosing.org). The Food and Drug Administration (FDA) updated the warfarin package label to include the use of pharmacogenetic testing in 2007.[99]

There are several barriers to the widespread application of pharmacogenomic testing for warfarin. First, and most important, is the INR. The ability to rapidly assess a patient's physiologic response to warfarin using an inexpensive and widely available test limits the need for pharmacogenomic information. Second is the timeliness of receiving pharmacogenomic test results. Pharmacogenomic information is most valuable when selecting the first 3 or 4 warfarin doses. However, pharmacogenomic testing outside of clinical trials may require several days or longer before results become available. Delaying warfarin initiation is rarely safe, thus pharmacogenomic test results are only meaningful if they are available in the first 2 to 3 days after treatment initiation. Although poor metabolizing CYP2C9 subtypes have been associated with increased risk of bleeding compared to the wild-type, clinical trials have not demonstrated improved bleeding or thromboembolic outcomes with the routine use of pharmacogenomic information to guide warfarin dosing when compared to usual care.[108,109] As a result, the clinical utility and cost-effectiveness of warfarin pharmacogenomics remains ill-defined and the American College of Chest Physicians guidelines does not recommend routine use.[110]

EVALUATION OF THERAPEUTIC OUTCOMES

Warfarin dose titration based on INR monitoring and UFH dose titration based on aPTT or anti-Xa monitoring allows a degree of personalized therapy not available with other anticoagulants. The intensity of warfarin or UFH therapy can be easily titrated in high-risk situations such as invasive procedures, accidental or intentional overdose, suspected nonadherence, or concomitant therapy with interacting drugs. Titrating DOAC therapy cannot be accomplished due to lack of readily available quantitative coagulation assays and dosing guidelines in these clinical scenarios.[111] In rare circumstances, such as patients who have previously had bariatric surgery, measuring trough levels of rivaroxaban or apixaban has been suggested.[105] This should be accomplished using an anti-Xa level specific to rivaroxaban or apixaban.

While laboratory coagulation monitoring is unnecessary during DOAC therapy, clinical surveillance is likely beneficial. In clinical trials comparing DOACs to warfarin, patients receiving DOAC therapy had regular contact with healthcare providers who screened for bleeding, changes in renal or hepatic function, drug adherence, potential drug interactions, and plans for invasive procedures.

Adherence is essential to preventing recurrent VTE during DOAC therapy due to their short half-lives. A study performed in patients with atrial fibrillation taking dabigatran found that pharmacist involvement during initial drug selection, patient education, and follow-up contacts improved drug adherence.[112] Pharmacist involvement during DOAC initiation may be especially important to ensure proper transitions from LMWH to dabigatran or edoxaban or from initiation to maintenance dosing with rivaroxaban or apixaban. An ABCDEF checklist may be helpful when monitoring patients on DOACs: A—Adherence with therapy, B—Bleeding risk assessment, C—Creatinine clearance/renal function monitoring, D—Drug interaction evaluation, E—Examination for adverse events and therapeutic effectiveness, and F-Final assessment and recommendations regarding the need for ongoing DOAC therapy.[113] What remains unclear is how frequently patient monitoring should be performed for patients on DOACs and whether it should be performed for all patients taking DOACs or only those at highest risk.

Because LMWH anticoagulant response is predictable when given subcutaneously, routine laboratory monitoring is unnecessary.[60] Prior to LMWH initiation, baseline complete blood cell counts with platelets and SCr should be obtained. If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.[79]

Antifactor Xa activity is the most widely used test to monitor the anticoagulant effect of LMWH in clinical practice. Routine antifactor Xa activity measurement is unnecessary in uncomplicated patients who are stable.[60] Measuring antifactor Xa activity may be considered in patients who are morbidly obese, pregnant, or have a significant renal impairment (eg, CrCl <30 mL/min [0.5 mL/s]).[60] However, many laboratories do not standardize the measurement of anti-factor Xa levels for specific LMWH products. For this reason and because the correlation between antifactor Xa levels and adverse outcomes is uncertain, guidelines recommend against measuring antifactor Xa activity in these situations.[5,114]

When antifactor Xa activity is used to monitor LMWH therapy, the sample should be drawn during the peak antifactor Xa activity—once a steady state has been achieved (after the second or third dose) and approximately 4 hours after the subcutaneous injection.[60] The antifactor Xa activity therapeutic range is not well-defined and has not been clearly correlated with efficacy or the risk of bleeding. For the treatment of VTE, an acceptable target range for the peak anti-Xa level for twice-daily enoxaparin dosing is 0.6 to 1 unit/mL (kU/L). For once-daily dosing, peak targets >1 unit/mL (kU/L) for enoxaparin and 1.05 units/mL (kU/L) for dalteparin have been suggested.[60] The target range for peak anti-Xa concentrations during cancer-associated VTE treatment with dalteparin is 0.5 to 1.5 units/mL(kU/L).[93]

Prior to initiating fondaparinux, baseline kidney function should be determined as fondaparinux is contraindicated when CrCL is <30 ml/min (0.5 mL/s).[62] Signs and symptoms of bleeding should be monitored daily, particularly in patients with a baseline CrCl between 30 and 50 mL/min (0.5 and

0.83 mL/s). If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.[62] The role of antifactor Xa monitoring during fondaparinux is not well-defined, but routine coagulation testing is not required.[62]

Administration of UFH requires close monitoring because each patient's anticoagulant response is unpredictable.[60] Although the aPTT has several limitations, most experts advocate using the aPTT to monitor UFH provided that institution-specific therapeutic ranges are defined.[60] The aPTT should be measured prior to the initiation of therapy to determine the patient's baseline. With IV infusion, the aPTT response to UFH therapy should be measured 6 hours after initiation or dose changes. UFH doses should be adjusted based on patient response and the institution-specific aPTT therapeutic range (Table 38-6).[60]

The PT measures the biologic activity of factors II, VII, and X and has been used for decades to monitor the anticoagulation effects of warfarin. The PT is performed by measuring the time required for clot formation after adding calcium and thromboplastin to citrated plasma.[72] Interpreting the PT is problematic because thromboplastins of differing sensitivity produce substantially different results, some of which could lead to inappropriate dosing decisions. The World Health Organization (WHO) addressed the need for standardization in the late 1970s by developing a reference thromboplastin and recommending the use of the INR to monitor warfarin therapy.[72] The INR attempts to correct for differences in thromboplastin reagents through the following formula:

$$\mathrm{INR} = \left(\frac{\mathrm{PT}^{\mathrm{patient}}}{\mathrm{PT}^{\mathrm{control}}}\right)^{\mathrm{ISI}}$$

INR=(PTpatientPTcontrol)ISI

The International Sensitivity Index (ISI) is a measure of thromboplastin responsiveness compared with the WHO reference standard.[72] Although the INR system has a number of limitations, it remains the preferred method for monitoring warfarin therapy.[72]

Referring patients with VTE to anticoagulation therapy management services is recommended to optimize the care of patients who take warfarin therapy by providing structured care, comprehensive patient education, and evaluation of outcomes.[5] When anticoagulation management services are not available, individual clinicians should strive to implement similar structured care processes.[110]

Portable finger-stick INR devices are available for monitoring warfarin therapy. These devices permit clinicians to do "real-time" therapeutic INR monitoring and enable patients to engage in self-testing at home.[5] Patients who engage in INR self-testing and warfarin self-management have fewer thromboembolic complications, report high levels of satisfaction with care, and maintain INRs within the therapeutic range slightly more frequently than those managed by "usual care." However, home INR testing and self-management is not for everyone and requires careful patient selection and considerable patient education.[110] Finger-stick INR devices are relatively expensive, but some patients qualify for insurance coverage for the monitor and testing supplies.

CONCLUSION

VTE is a significant public health issue, yet there is little public awareness of the life-threatening nature of this commonly occurring condition. Given the number and variety of clinical circumstances that place individuals at risk for VTE, improvements in VTE prevention and care have the potential to benefit many patients. Over the past decade, the focus on quality healthcare has included systematic measures to improve the use of effective VTE prophylaxis and evidence-based VTE treatments. The concerted efforts of government and accrediting agencies working with hospitals and other healthcare institutions will hopefully reduce VTE rates. Systematic approaches to this problem are needed at every level, starting with increased public and health practitioner awareness, continuing with the uniform use of effective prophylactic strategies in patients at risk, and concluding with the application of high-quality VTE treatment strategies

ABBREVIATIONS

aPC	activated protein C
aPTT	activated partial thromboplastin time
β_2-gp	β_2-glycoprotein

BMI	body mass index
CrCl	creatinine clearance
CTPA	computed tomography pulmonary angiography
CTPH	chronic thromboembolic pulmonary hypertension
CUS	compression ultrasound
CYP	cytochrome P450
DOAC	direct-acting oral anticoagulant
DVT	deep vein thrombosis
FFP	fresh-frozen plasma
HIT	heparin-induced thrombocytopenia
INR	international normalized ratio
IPC	intermittent pneumatic compression
ISI	International Sensitivity Index
IVC	inferior vena cava
LMWH	low-molecular-weight heparin
NICE	National Institute for Health and Care Excellence
PCCs	prothrombin complex concentrates
PE	pulmonary embolism

SELF-ASSESSMENT QUESTIONS

1. XT is a 55-year-old male (height = 63 in. [160 cm], weight = 80 kg) who presents to the Emergency Department (ED) and is diagnosed with a new unprovoked left lower extremity deep vein thrombosis (DVT) and pulmonary embolism (PE). The patient has no significant past medical history and takes no other medications. All baseline labs are within normal limits and the patient is hemodynamically stable. Which of the following is the best initial treatment regimen for XT upon discharge from the ED?

   A. Enoxaparin 80 mg subcutaneously BID × 5 days + edoxaban 60 mg PO daily

   B. Enoxaparin 80 mg subcutaneously BID × 5 days then edoxaban 60 mg PO daily

   C. Enoxaparin 120 mg subcutaneously BID × 5 days + warfarin 5 mg PO daily

   D. Enoxaparin 120 mg subcutaneously daily × 5 days then warfarin 5 mg PO daily

2. Which of the following is a factor when considering a direct oral anticoagulant (DOAC) for the treatment of venous thromboembolism (VTE)?

   A. History of hypertension requiring losartan therapy

   B. History of epilepsy requiring carbamazepine therapy

   C. History of heart failure requiring furosemide therapy

   D. History of hypothyroidism requiring levothyroxine therapy

3. A 70-year-old male patient with DVT and a baseline international normalized ratio (INR) of 1.1 is started on warfarin 5 mg daily on day 1 and day 2 as well as enoxaparin 80 mg SC BID. The patient has no history of malignancy, malnutrition, heart failure, alcohol abuse, or liver dysfunction. INR today (day 3) is 1.5. Which of the following reflects the best warfarin dose for day 3?

   A. 10 mg

   B. 5 mg

   C. 1 mg

   D. HOLD warfarin today

4. Which one of the following statements best describes how a patient should interpret their INR results?

   A. When the INR is below 2.0 she is at increased risk for bleeding.

   B. When the INR is between 2 and 3 she needs to eat less vitamin K-containing food in her diet.

   C. When the INR is below 2.0 her dose of warfarin may need to be adjusted.

   D. When the INR is higher than 3.0 she is at increased risk for having another VTE.

5. NB is a 57-year-old 5’8” (173 cm) female weighing 60 kg admitted to the hospital for elective total knee replacement surgery. Past medical history includes anxiety and hypertension. Prescription medications include lisinopril 20 mg daily and paroxetine 20 mg daily. Preoperative labs include: BUN 28 mg/dL (10.0 mmol/L) and SCr 1.1 mg/dL (97 μmol/L). Which of the following is the best recommendation for pharmacological VTE prophylaxis to reduce NB’s VTE risk following her knee replacement surgery?

   A. Enoxaparin 60 mg subcutaneously BID

   B. Dabigatran 150 mg twice daily

   C. Rivaroxaban 10 mg PO daily

D. Edoxaban 30 mg PO QD

6. Which of the following is the most appropriate duration of apixaban therapy for a patient who experienced a first DVT following knee replacement surgery?

   A. 6 weeks

   B. 3 months

   C. 6 months

   D. Indefinite

7. Which of the following is the most appropriate drug to administer for bleeding due to an accidental warfarin overdose?

   A. Vitamin K

   B. Protamine

   C. Idarucizumab

   D. Andexanet

8. SJ is a 76-year-old male (height = 69 in. [175 cm], weight = 105 kg) who is diagnosed with PE. Current medications include: lisinopril 40 mg PO daily, hydrochlorothiazide 25 mg PO daily, atorvastatin 40 mg PO daily. Labs include BUN 26 mg/dL (9.3 mmol/L) and serum creatinine (SCr) 2.3 mg/dL (203 μmol/L). What is the best recommendation for initial parenteral anticoagulant treatment for SJ's acute PE?

   A. Fondaparinux 10 mg subcutaneously daily

   B. Dalteparin 5,000 units subcutaneously daily

   C. Enoxaparin 100 mg subcutaneously twice daily

   D. Unfractionated heparin (UFH) 10,000 unit bolus with 2,000 units/hr continuous infusion

9. A patient's INR is 1.6 following a significant dietary change. Which of the following is the most likely explanation for today's lab result?

   A. Eating more dark green leafy vegetables than usual

   B. Eating fewer dark green leafy vegetables than usual

   C. Drinking grapefruit juice

   D. Drinking cranberry juice

10. Which of the following is the most appropriate anticoagulant to treat VTE during pregnancy?

    A. Warfarin

    B. Dabigatran

    C. Enoxaparin

    D. UFH

11. A 66-year-old male presents with unilateral leg pain, redness, and swelling. Past medical history is significant for hypertension. D-dimer is elevated. Which of the following is the most appropriate next step?

- A. UFH
- B. Apixaban
- C. Compression ultrasound
- D. Computed tomography pulmonary angiography

12. In which of the following clinical scenarios would anti-Xa monitoring be recommended during low-molecular-weight heparin (LMWH) treatment?
    - A. Initial DVT treatment for a patient weighing 120 kg
    - B. Initial PE treatment in an 80-year-old female with renal dysfunction
    - C. VTE prophylaxis in a patient with cancer
    - D. Long-term PE treatment in a pregnant patient
13. Which of the following is not a risk factor for DVT in hospitalized patients?
    - A. Cancer
    - B. Hypertension
    - C. Age >70 years
    - D. Estrogen therapy
14. Which of the following should be included in patient education for outpatient DVT treatment with enoxaparin and warfarin?
    - A. Avoiding vitamin K-rich foods
    - B. Interpreting INR results
    - C. Discontinuing enoxaparin therapy in 3 days
    - D. Injecting enoxaparin with the needle at a 45° angle to the skin
15. Which of the following is the most appropriate VTE prophylaxis strategy for a general surgery patient at high risk of VTE with ongoing bleeding?
    - A. Aspirin
    - B. Edoxaban
    - C. Inferior vena cava filter
    - D. Intermittent pneumatic compression devices

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** is the correct answer because the dose of enoxaparin is appropriate based on the patient's weight and is followed by the appropriate dose of edoxaban. Answer A is incorrect because edoxaban and enoxaparin should not be overlapped. Answer C is incorrect because the enoxaparin dose is too high. Answer D is incorrect because warfarin and enoxaparin should be overlapped for at least 5 days and until the INR is above 2.

2. **B.** is the correct answer because carbamazepine is a strong inducer of CYP 3A4 and P-gp and could potentially result in subtherapeutic DOAC concentrations and therapeutic failure. None of the medications or medical conditions in Answers A, C, or D are known to influence DOAC concentrations. See subsection "Direct Oral Anticoagulants" under section "Drug Class Information" for additional information.

3. **B.** is the correct answer because the patient's INR is beginning to increase but not too rapidly. The INR is not expected to reach the therapeutic range until 5 to 7 days on an appropriate warfarin dose so this response seems reasonable. Answer A is incorrect because increasing the warfarin dose may result in an INR>3 in a few days. Answers C and D are incorrect because lowering or holding the warfarin dose will prolong the time required to reach an INR of 2 and hence the duration of enoxaparin injections. See subsection "Warfarin" under section "Drug Class Information" for additional details.

4. **C.** is the correct answer because INRs outside the usual therapeutic range of 2.0 to 3.0 indicate the possible need for warfarin dose adjustment. Answer A is incorrect because an INR below 2.0 indicates an increased risk for recurrent VTE. Answer B is incorrect because an INR in the therapeutic INR range indicates that the patient should make no changes to the amount of vitamin K-containing food she is eating. Answer D is incorrect because an INR above 3.0 indicates increased bleeding risk. See subsection "Warfarin" under section "Drug Class Information" for additional details.

5. **C.** is the correct answer because the rivaroxaban dose for VTE prophylaxis is correctly identified. Answer A is incorrect because the enoxaparin dose for VTE prophylaxis following orthopedic surgery is 30 mg subcutaneously BID. Answer B is incorrect because the dose listed is for stroke prevention in atrial fibrillation. Answer D is incorrect because edoxaban is not indicated for surgical VTE prophylaxis.

6. **B.** is the correct answer because it correctly identifies the duration of therapy recommended by consensus guideline panels following a surgically provoked DVT. Answer A is incorrect because the duration of therapy is too short. Answers C and D are incorrect because the duration of therapy is too long. See section "General Approach to the Treatment of Venous Thromboembolism" for additional details.

7. **A.** is the correct answer because vitamin K will bypass the inhibition of clotting factor synthesis produced by warfarin and restore clotting factor function. Answer B is incorrect because protamine reverses the effects of UFH, not warfarin. Answer C is incorrect because idarucizumab reverses the effects of dabigatran, not warfarin. Answer D is incorrect because andexanet reverses the effect of direct Xa inhibitors, not warfarin. See Table 38-12 and subsection on warfarin under section "Drug Class Information" for additional details.

8. **D.** is the correct answer because UFH is not reliant on the patient's kidney function for elimination and this patient has a creatinine clearance below 30 mL/min (0.5 mL/s). Answer A is incorrect because fondaparinux is contraindicated when creatinine clearance is <30 mL/min (0.5 mL/s). Answer B is incorrect because dalteparin is cleared by the kidneys and the dose listed is for VTE prophylaxis, not treatment. Answer C is incorrect because the enoxaparin dose has not been adjusted for creatinine clearance <30 mL/min (0.5 mL/s). See subsections on fondaparinux, LMWH, and UFH under section "Drug Class Information" for additional details.

9. **A.** is the correct answer because dark green leafy vegetables are a rich source of vitamin K, which can lower the INR. Answer B is incorrect because eating LESS dietary vitamin K would result in the INR going higher, not lower. Answer C is incorrect because drinking grapefruit juice will probably have no effect on the INR but is a CYP enzyme inhibitor and would therefore be expected to increase the INR if there was an effect on the INR. Answer D is incorrect because cranberry juice is unlikely to have any appreciable effect on the INR. See subsection on warfarin in "Drug Class Information" for additional details.

10. **C.** is the correct answer because enoxaparin does not cross the placenta and has been shown to be safe during pregnancy. Answer A is incorrect because warfarin is a known teratogen. Answer B is incorrect because DOACs are not recommended in pregnancy because they cross the placenta and also have not been well studied in pregnancy. Answer D is incorrect because although UFH doesn't cross the placenta, it can cause osteoporosis when used for prolonged periods of time at therapeutic doses as would likely be required during pregnancy-related VTE treatment. See subsection "Pregnancy" under section "Special Populations" and Table 38-10 for additional detail.

11. **C.** is the correct answer because elevated D-dimer cannot reliably be used to confirm DVT diagnosis, it is most appropriately used to rule out DVT—compression ultrasound is the correct imaging test to diagnose DVT. Answers A and B are incorrect because anticoagulation should not be initiated until DVT is objectively confirmed. Answer D is incorrect because computed tomography scanning is generally used to diagnose PE, not DVT.

12. **D.** is the correct answer; measuring antifactor Xa activity may be considered in patients who are pregnant. Answer A and B are incorrect because current guidelines recommend against the routine use of anti-Xa monitoring in obesity (answer A) and renal dysfunction (answer B). Routine antifactor Xa monitoring is not necessary in patients with cancer (answer C). See section "Evaluation of Therapeutic Outcomes" for additional detail.

13. **B.** is the correct answer because of the available choices it is the only one that is NOT a recognized risk factor for DVT in hospitalized patients. See Table 38-1 for additional detail.

14. **B.** is the correct answer because it is important that patients are aware of what their INR results mean. Answer A is incorrect because dietary vitamin K intake should be consistent, not avoided. Answer C is incorrect because enoxaparin must be overlapped with warfarin for at least 5 days and only if the INR is above 2.0. Answer D is incorrect because enoxaparin should be injected at a 90-degree angle to the skin.

15. **D.** is correct because it has the lowest associated bleeding risk. Answers A and B are incorrect because they would affect the hemostatic system and further increase bleeding risk in this patient. Answer C is incorrect because inferior vena cava filters are associated with increased DVT risk long-term and a safer, less invasive option is available.

Chapter 39: Stroke

Melody Ryan; Melissa Nestor

KEY CONCEPTS

KEY CONCEPTS

①Stroke can be either ischemic (87%) or hemorrhagic (13%) and the two types are treated differently.

②Transient ischemic attacks (TIAs) require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.

③In patients with an ischemic stroke and a blood pressure (BP) <220/120 mm Hg without comorbid conditions requiring acute hypertensive treatment, the acute lowering of BP in the first 48 to 72 hours after stroke onset does not improve survival or the level of dependency; “permissive hypertension” (BP up to 220/120 mm Hg) is often allowed. In patients with intracranial hemorrhage and elevated systolic blood pressure (SBP) between 150 and 220 mm Hg, the acute lowering of SBP to lower than 140 mm Hg is safe and may improve functional outcomes.

④Thrombectomy is strongly recommended for patients with anterior circulation arterial occlusion in the internal carotid artery (ICA) or the M1 segment of the middle cerebral artery (MCA) who are within 6 hours of symptom onset and may be considered in select patients within 6 to 24 hours of symptom onset.

⑤In patients with ischemic stroke and 70% to 99% stenosis of the carotid artery, carotid endarterectomy or carotid stenting should be performed.

⑥Early pharmacologic reperfusion (initiated less than 4.5 hours from symptom onset) with intravenous alteplase has been shown to improve functional ability after ischemic stroke.

⑦Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of noncardioembolic ischemic stroke.

⑧Oral anticoagulation is recommended for the secondary prevention of cardioembolic stroke in moderate- to high-risk patients.

⑨Elevated blood pressure is very common in ischemic stroke patients and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.

⑩Statin therapy is recommended for all ischemic stroke patients, regardless of baseline cholesterol, to reduce stroke recurrence.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “What is a stroke?” (https://youtu.be/QIAI6KOwKII">https://youtu.be/QIAI6KOwKII) in Khan Academy. This 11-minute video provides an overview of stroke and is useful to enhance understanding of stroke pathophysiology.

INTRODUCTION

Stroke is the leading cause of disability among adults and the fifth leading cause of death in the United States, behind cardiovascular disease, cancer, unintentional injuries, and chronic lower respiratory diseases.[1] Although the incidence of stroke has been trending downward, approximately 795,000 strokes occur annually, contributing to nearly 148,000 deaths each year.[2] Aggressive efforts to organize stroke care at the local and regional levels and increased utilization of evidence-based recommendations and national guidelines may have contributed to the improved outcomes.

EPIDEMIOLOGY

There are about 7.6 million stroke survivors in the United States and stroke is the leading cause of adult disability, with women having worse outcomes than men.[2] Owing in part to the need for expensive posthospitalization rehabilitation and nursing home care, the annual cost of stroke in the United States is estimated to be nearly $50 billion.[2]

Not all groups have benefitted equally from advances in care and prevention of stroke. Black Americans have stroke rates that are 1.5 times higher than White Americans; rates are up to four times higher at younger ages.[2] Genome-wide studies provide some evidence that part of this racial disparity is genetic. However, age-adjusted death rates for stroke are still 1.6 times higher for Black men compared to White men and 1.3 times higher for Black women compared to White women.[2] In addition, geographic disparity in stroke incidence exists, such that many states in the southeastern United States have stroke mortality rates 30% to 40% higher than the national average.[2] Lastly, case fatality due to hemorrhagic stroke has not declined in the past decade, with 30-day rates remaining around 46%.[2]

ETIOLOGY

① Stroke is subdivided into either ischemic or hemorrhagic types (87% and 13%, respectively).[2] Hemorrhagic stroke includes subarachnoid hemorrhage (SAH) and intracerebral hemorrhage (ICH). SAH occurs when blood enters the subarachnoid space, which can occur due to trauma, rupture of an intracerebral aneurysm, or rupture of an arteriovenous malformation (AVM). ICH, however, occurs when bleeding occurs in the brain parenchyma itself, with the formation of a hematoma within the brain. Uncontrolled hypertension is the most common cause for ICH, but antithrombotic therapy, cerebral amyloid angiopathy, and some drugs of abuse are also associated with ICH.[3] Hemorrhagic stroke, though less frequent in occurrence, has significantly higher mortality than ischemic stroke and is dependent on the quality and availability of critical care. In high-income countries, the mortality rate is 25% to 30%, but it is 30% to 48% in low- and middle-income countries.[3]

Ischemic stroke is caused by occlusion within a cerebral artery or emboli from a more proximal source resulting in occlusion of a cerebral artery. Atherosclerosis of large arteries, either intracranial or extracranial, as well as small artery damage, can give rise to ischemic stroke. Emboli can also arise centrally from the heart in patients with atrial fibrillation, valvular heart disease, or other prothrombogenic heart problems and are responsible for approximately 25% of ischemic stroke. While large artery atherosclerosis, small artery disease, and cardioembolism comprise the majority of ischemic stroke mechanisms, the cause of stroke is undetermined in some cases.[2] Determining the stroke mechanism (eg, cardiogenic mechanism vs other causes) is important when selecting the most appropriate long-term pharmacotherapy in stroke patients.

Risk Factors

Risk factors for ischemic stroke can be described as nonmodifiable or modifiable, with some risk factors more well-documented than others. The main risk factors of ischemic stroke are listed in TABLE 39-1.[4] The risk of stroke doubles for each decade older than 55 years. Men are at a higher risk of ischemic stroke than women at a younger age, but women have higher mortality and lifetime risk of ischemic stroke overall. Individuals who identify as

Black, Asian-Pacific Islanders, or Hispanic have higher rates of death from ischemic stroke compared to those who identify as White.[4] Recommendations for ischemic stroke prevention focus on aggressive management of modifiable, well-documented risk factors.

TABLE 39-1

Risk Factors for Ischemic Stroke

Nonmodifiable Risk Factors

- Age
- Race
- Sex
- Low birth weight
- Genetic Factors

Modifiable, Well Documented

- Cigarette Smoking
- Hypertension
- Diabetes
- Asymptomatic carotid stenosis
- Dyslipidemia
- Atrial fibrillation
- Sickle cell disease
- Poor diet
- Obesity
- Physical inactivity
- Other cardiac diseases (coronary heart disease, heart failure, peripheral arterial disease)

Potentially Modifiable, Less Well Documented

- Migraine
- Metabolic syndrome
- Drug and alcohol abuse
- Inflammation and infection
- Elevated lipoprotein (a)
- Homocysteinemia
- Patent foramen ovale
- Sleep-disordered breathing

Data from Reference 4.

The most common modifiable, well-documented risk factors for ischemic stroke include hypertension, cigarette smoking, diabetes, atrial fibrillation, and dyslipidemia. Hypertension is the most common risk factor, affecting up to one in three adults in the United States. Cardiac disease, including coronary artery disease, heart failure, left ventricular hypertrophy, and particularly atrial fibrillation, is also a very important risk factor. Atrial fibrillation increases an individual's risk of ischemic stroke to 5% to 20% per year, depending on concomitant comorbidities. Diabetes mellitus, dyslipidemia, and cigarette smoking contribute to atherogenic disease and increase the risk of ischemic stroke.[4]

PATHOPHYSIOLOGY

Ischemic Stroke

Ischemic stroke is the manifestation of neurologic deficit due to occlusion of a cerebral artery, causing a reduction in cerebral blood flow and neuronal ischemia. The pathophysiologic mechanisms of ischemic stroke are depicted in Fig. 39-1. These arterial occlusions are most commonly due to artery-to-artery emboli, cardiac sources of emboli, or by vascular changes leading to occlusion of the cerebral artery itself. Cerebral blood flow is maintained at an average rate of 50 mL/100 g per minute over a wide range of blood pressure (mean arterial pressures of 50-150 mm Hg) by a process called cerebral autoregulation. Cerebral blood vessels dilate and constrict in response to changes in blood pressure, but this process can be impaired by atherosclerosis, chronic hypertension, and acute injury, such as stroke. Decreased cerebral blood flow due to arterial occlusion can lead to infarction of cerebral tissue. Surrounding a core area of infarct is tissue that is ischemic but may maintain membrane integrity and is referred to as the *ischemic* penumbra.[5] This penumbra is the area of brain tissue that is potentially salvageable with urgent pharmacologic and endovascular interventions in acute ischemic stroke.

FIGURE 39-1

Pathophysiology of ischemic stroke. Diagram illustrating the three major mechanisms underlying ischemic stroke including occlusion of an intracranial vessel by an embolus that arises from a distant site (eg, cardiogenic embolus), in situ thrombosis of an intracranial vessel, typically affecting the small penetrating arteries, and hypoperfusion caused by flow-limiting stenosis of a major extracranial artery. Insufficient oxygen supply in ischemic tissue leads to adenosine triphosphate (ATP) depletion and anaerobic metabolism. This results in an accumulation of intracellular lactate, sodium, and water, which may cause cytotoxic edema and eventual cell lysis. There is also an influx of intracellular calcium leading to activation of lipases and proteases that degrade proteins and release free fatty acids from cellular membranes.

Additionally, excitatory amino acids, such as glutamate and aspartate, are released in ischemic tissue that perpetuate neuronal damage and production of damaging prostaglandins, leukotrienes, and reactive oxygen species. These processes occur within 2 to 3 hours from the onset of ischemia and, ultimately, lead to cellular apoptosis and necrosis.[5]

Hemorrhagic Stroke

Hemorrhagic stroke causes neuronal damage by a variety of mechanisms and timelines. In patients with ICH, the hematoma causes primary injury and mechanical compression of the brain parenchyma itself. Early hematoma expansion, which may occur in up to 38% of patients within 3 hours of ICH onset, is associated with worsened functional outcome and increased mortality. The highest rates of mortality are associated with a low Glasgow Coma Score (GCS) on presentation (GCS 3-4), ICH volume greater than 30 cc (mL), intraventricular extension, brain stem location, and age greater than 80.[6] Secondary mechanisms of injury in ICH patients are mediated by subsequent inflammatory response, cerebral edema, and damage from blood product degradation.[3]

CLINICAL PRESENTATION

The term stroke describes patients with an episode of neurologic dysfunction caused by focal cerebral, spinal, or retinal infarction. The syndrome of arterial ischemia with transient symptoms (<24 hours) and without evidence of infarction is a transient ischemic attack (TIA). Appropriate patient history obtainment helps determine the nature of symptom onset and duration of neurologic dysfunction. The location of the central nervous system (CNS) injury and its reference to a specific arterial distribution in the brain are determined through neurologic examination and confirmed by imaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI). The main arterial supply to the cerebral hemispheres is illustrated in Fig. 39-2 and Fig. 39-3. Vascular imaging with computed tomography angiography (CTA) can aid clinicians in determining the cause of stroke and whether urgent mechanical intervention is necessary.

CLINICAL PRESENTATION: Stroke

General

- The patient may not be able to reliably report the history due to cognitive or language deficits. A reliable history may have to come from a family member or witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, vertigo, and/or falling. Ischemic stroke is not usually painful, but some patients may complain of headache. Pain and headache, often severe, are more common with hemorrhagic stroke.

Signs

- The specific areas of neurologic deficit are determined by the area of the brain involved.
- Hemiparesis or monoparesis occurs commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from dysarthria, visual field deficits, and altered levels of consciousness.

Laboratory Tests

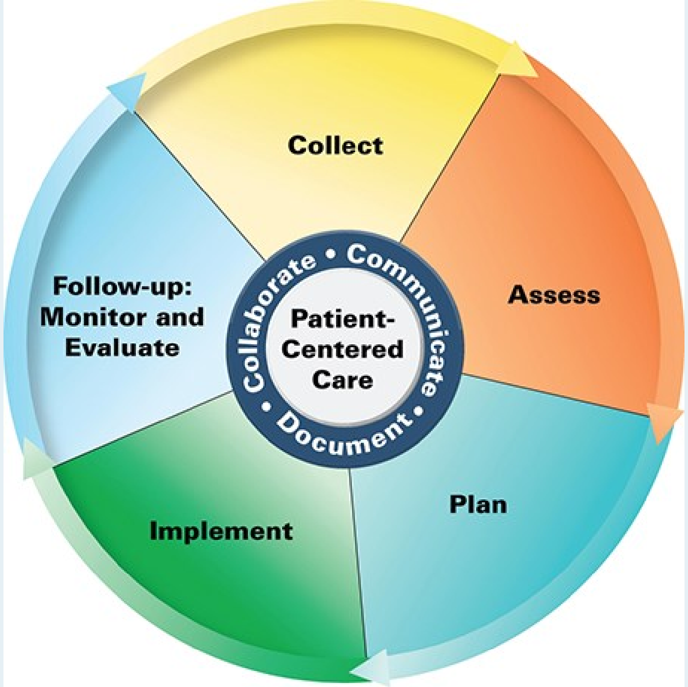
- In acute stroke, assessment of blood glucose, platelet count, and coagulation parameters (eg, prothrombin time, aPTT) are used to determine treatment eligibility.
- Tests for hypercoagulable states (protein C/S deficiency, antiphospholipid antibody) should be done only when the cause of the stroke cannot be determined based on the presence of well-known risk factors.

Other Diagnostic Tests

- CT scan of the head will reveal an area of hyperdensity (white) in patients with hemorrhage and will be normal or hypodense (dark) in patients with infarction. It may take 24 hours before the CT scan will reveal the area of infarction.
- MRI of the head will reveal areas of ischemia with higher resolution and an MRI with diffusion-weighted imaging (DWI) will reveal an evolving infarct within minutes of stroke onset.
- Vascular imaging with CTA is recommended in patients with endovascular treatment indications. CTA can identify both acute treatment candidacy as well as identify intracranial and extracranial arterial stenosis.
- An ECG can help determine whether the patient is presenting in atrial fibrillation.
- TTE can identify cardiac valve abnormalities or wall-motion abnormalities as sources of emboli to the brain. A “bubble study” in which a solution with tiny bubbles is injected intravenously can be done to look for an intra-arterial shunt indicating an atrial-septal defect or a patent foramen ovale. The bubbles can be seen moving through the heart chambers during the TTE.
- In patients unable to undergo CTA, carotid Doppler (CD) and transcranial Doppler (TCD) can be used to determine extracranial carotid artery stenosis and intracranial artery stenosis.

PATIENT CARE PROCESS

Patient Care Process for Acute Ischemic Stroke



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, race)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use)
- Current medications including nonprescription aspirin/nonsteroidal anti-inflammatory drug (NSAID) use, herbal products, dietary supplements, and prior antiplatelet and anticoagulant medication use
- Medication allergies
- Symptoms (time of onset, duration)
- Objective data
  - Blood pressure (BP), heart rate, respiratory rate, height, weight
  - Labs including hemoglobin, platelets, serum creatinine, activated partial thromboplastin time (aPTT), prothrombin time, blood glucose, troponin
  - Noncontrast computed tomography (CT) scan, magnetic resonance imaging (MRI), and/or computed tomography angiography (CTA) may be needed
  - Neurologic examination (eg, National Institutes of Health Stroke Scale [NIHSS] score)
  - Electrocardiogram (ECG) and, in some patients, transthoracic echocardiogram (TTE)

Assess

- Hemodynamic stability (eg, systolic blood pressure [SBP] <110 mm Hg, diastolic blood pressure [DBP] <185 mm Hg, if candidate for tissue plasminogen activator candidate; otherwise, BP less than 220/120 mm Hg; O_2-sat >94% [0.94]; temperature <38°C [100.4°F])

- Blood glucose (<60 mg/dL [3.7 mmol/L] or >180 mg/dL [10.0 mmol/L] should be treated)
- Presence of active bleeding and/or bleeding risk factors (Table 39-6)
- Patient's candidacy for tissue plasminogen activator treatment (Table 39-2)or thrombectomy
- Presence of dysphagia (swallowing disorder)

Plan

- Aspirin within 24 to 48 hours unless contraindicated; delay for 24 hours if the patient has been given tissue plasminogen activator
- Antiplatelet drug therapy regimen including specific medication(s), dose, frequency, and duration OR oral anticoagulant, if the patient has atrial fibrillation (see Table 39-2)
- Evaluation for carotid endarterectomy or carotid stenting
- Prophylaxis for venous thromboembolism, if immobile
- Nutritional plan; if the patient has dysphagia, nutrition via nasogastric tube or percutaneous gastrostomy tube
- Treat and manage stroke risk factors (Table 39-2) (eg, BP control, dyslipidemia, diabetes)
- Monitoring parameters including efficacy (eg, stroke symptoms) and safety (eg, signs and symptoms of bleeding [all antiplatelets and oral anticoagulants], headache [dipyridamole]); frequency and timing of follow-up
- Patient education (eg, the purpose of treatment, dietary and lifestyle modification, invasive procedures, drug-specific information, medication administration)
- Self-monitoring for stroke recurrence, the occurrence of bleeding, and when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, physical therapist, occupational therapist, behavioral health, dietician)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Improvement of stroke symptoms; neurological examination
- Presence of adverse drug reactions (eg, bleeding [all medications], gastrointestinal upset [aspirin], headache [dipyridamole], cerebral edema, seizures)
- Patient adherence to treatment plan using multiple sources of information
- Adherence to recommended follow-up appointments (eg, neurology, physical therapy)
- Assess for poststroke depression

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

The goals of treatment of acute stroke are to (a) minimize the ongoing neurologic injury in the acute setting to reduce mortality and long-term disability, (b) prevent complications secondary to immobility and neurologic dysfunction, and (c) prevent stroke recurrence. Primary prevention of stroke is described in the Chapter 30 (Hypertension), Chapter e31 (Acute Hypertensive Crisis), and Chapter 32 (Dyslipidemia).[4]

General Approach to Treatment

②③ Patients with presumed acute stroke should have a CT scan performed urgently to identify the type of injury (eg, ischemic or hemorrhagic), provided respiratory and cardiac indices are stable. Ischemic stroke patients presenting within hours of symptom onset should be evaluated for pharmacologic and mechanical reperfusion therapy. Patients with TIA require urgent assessment and intervention to reduce the risk of stroke, which is highest in the first few days after TIA.[4]

In the absence of comorbid conditions, in patients with an acute ischemic stroke and uncontrolled hypertension with a BP <220/120 mm Hg, acutely lowering BP in the first 48 to 72 hours does not prevent death or improve the level of dependency. Therefore, “permissive hypertension” is often part of routine care in these patients. However, for patients who are candidates for alteplase or those with comorbid conditions, such as aortic dissection, acute myocardial infarction, pulmonary edema, or hypertensive encephalopathy, treatment of acute hypertension may be required. If BP is treated, the use of short-acting and easily titrated agents, such as labetalol or nicardipine/clevidipine, is preferred. See Chapter e31 - Acute Hypertensive Crisis. Table 39-2 outlines current recommendations regarding the management of arterial hypertension in patients with acute ischemic stroke. In patients with ICH and elevated BP, the acute lowering of SBP to 140 mm Hg has been shown to be safe and may improve functional outcome.[6]

TABLE 39-2

Blood Pressure Treatment Guidelines in Stroke

Recommendation	Class (Strength) of Recommendation[a]	Level (Quality) of Evidence[b]
Ischemic Stroke with Alteplase Treatment		
• Pre-alteplase: lower BP to SBP <185 mm Hg and DBP <110 mm Hg • Post-alteplase: maintain SBP <180 mm Hg and DBP <105 mm Hg for 24 hours	I	B-NR
Ischemic Stroke without Alteplase Treatment		
• Treatment benefit uncertain/not recommended unless BP >220/120 mm Hg • If comorbid conditions (eg, acute coronary event, acute heart failure, aortic dissection, symptomatic intracranial hemorrhage, preeclampsia/eclampsia) are present that require acute lowering of BP, lowering BP by 15% is probably safe)	IIb I	C-EO C-EO
Ischemic Stroke with Mechanical Thrombectomy without Fibrinolytic Treatment		
• It is reasonable to maintain BP ≤ 185/110 mm Hg before the procedure	IIb	C-EO
Intracranial Hemorrhage		
• Treatment is reasonable for ICH patients with SBP >220 mm Hg • For ICH patients with SBP 150-220 mm Hg, acute lowering of SBP to 140 mm Hg is safe	IIb I	C A
Pharmacologic Options for Blood Pressure Lowering in Acute Stroke		
• Labetalol 10-20 mg IV over 1-2 minutes, may repeat • Nicardipine 5 mg/hr IV, titrate up by 2.5 mg/hr every 5-15 minutes, maximum 15 mg/hr • Clevidipine 1-2 mg/hr IV, titrate by doubling the dose every 2-5 minutes, maximum 21 mg/hr • Other agents to consider: hydralazine, enalaprilat, nitroprusside IV infusion, labetalol IV infusion	IIb	C-EO

ASCVD, atherosclerotic cardiovascular disease; BMI, body mass index; GLP1, glucagon-like peptide 1; HbA1c, hemoglobin A1c; ICH, intracerebral hemorrhage; INR, international normalized ratio; IV, intravenous; LDL, low-density lipoprotein; NIHSS, National Institutes of Health Stroke Scale.

Data from References 6 and 7.

[a] Class (strength) of recommendation : I, strong; IIa, moderate; IIb, weak; III, no benefit (moderate); 3, harm (strong).

[b] Level (quality) of evidence: A, high-quality evidence from more than 1 randomized clinical trial, meta-analyses of high-quality randomized clinical trials, or one or more randomized clinical trials corroborated by high-quality registry studies; B-R (randomized), moderate-quality evidence from one or more randomized clinical trials or meta-analyses of moderate-quality randomized clinical trials; B-NR (nonrandomized), moderate-quality evidence from one or more well-designed, well-executed nonrandomized studies, observational studies, or registry studies or meta-analyses of such studies; C-LD (limited data), randomized or nonrandomized observational or registry studies with limitations or design or execution, meta-analyses of such studies, or physiological or mechanistic studies in human subjects; C-EO (expert opinion), consensus of expert opinion based on clinical experience.

[c]Very high risk of future ASCVD events includes a history of multiple major ASCVD events or 1 major ASCVD event and multiple high-risk conditions. Major ASCVD events are history of ischemic stroke, acute coronary syndrome within the past 12 months, history of myocardial infarction, symptomatic peripheral arterial disease. High-risk conditions include: age ≥65 years; heterozygous familial hypercholesterolemia; history of coronary artery bypass surgery or percutaneous coronary intervention outside of the major ASCVD events; diabetes; hypertension; chronic kidney disease; current smoking.

Once the patient is out of the hyperacute phase (e.g. first 24 hours), management is focused on preventing worsening of stroke, minimizing complications, and secondary prevention. The acute phase of the stroke includes the first week after the event.[4]

Nonpharmacologic Therapy

Ischemic Stroke

④ To reperfuse ischemic brain tissue, endovascular intervention and thrombectomy is recommended by the American Heart Association (AHA)/American Stroke Association (ASA) since 2015 based on data from several clinical trials.[7] Thrombectomy is strongly recommended for patients with anterior circulation arterial occlusion in the ICA or the M1 segment of the MCA who are within 6 hours of symptom onset and may be considered in select patients within 6 to 24 hours of symptom onset. Patients with ICA and M1 MCA arterial occlusions and symptom onset within 24 hours may be candidates for endovascular intervention if imaging studies suggest a significant area of salvageable penumbra is present. The benefit of mechanical thrombectomy is less clear in patients with posterior circulation occlusions and should be considered in a case-by-case basis.[7] The availability of this mechanical intervention for stroke has greatly increased the importance of early vascular diagnostic imaging followed by rapid transfer to centiers with interventional capabilities and escalation of care in patients with these emergent large vessel occlusions.

Large infarcts of the MCA are often devastating and, in patients without recanalization via pharmacologic or mechanical intervention, are associated with high rates of morbidity and mortality. Decompressive hemicraniectomy is a surgical procedure that can be done to reduce intracranial pressure, typically due to cerebral edema, and can reduce mortality and improve functional outcome. In patients under 60 years of age with unilateral MCA infarcts and significant cerebral edema, surgical intervention with decompressive craniectomy has been shown to reduce mortality by almost 50% and improve favorable neurologic outcomes at one year. This surgical intervention can be considered for patients over the age of 60 but the likelihood of favorable neurologic outcome is less robust. In patients with cerebellar infarction and significant swelling, surgical decompression can be lifesaving. For all ischemic stroke patients coordinated care with a multidisciplinary approach to assessment and early rehabilitation is effective in reducing overall disability due to stroke.[7]

⑤ For the secondary prevention of ischemic stroke, carotid endarterectomy of an ulcerated and/or stenotic carotid artery is a very effective way to reduce stroke incidence and recurrence in patients with 70% to 99% stenosis if performed in centers with low operative morbidity and mortality.[8] Carotid stenting is a less invasive alternative that can be effective in reducing recurrent stroke risk when combined with aspirin and clopidogrel therapy.[8] However, it is associated with a higher periprocedural stroke rate.[8]

A patent foramen ovale (PFO) occurs when the septum between the right and left atria fails to close after birth. A PFO is present in 20% to 25% of adults; but in patients with stroke from unknown causes, 40% to 50% have a PFO.[9] The PFO can be closed surgically. People who benefit most from this surgery are 18 to 60 years of age with nonlacunar ischemic strokes of undetermined cause.[8]

Other nonpharmacological approaches for secondary stroke prevention include diet modification, exercise, smoking cessation, avoidance of environmental tobacco smoke, moderation of alcohol consumption, and avoidance of stimulants such as amphetamines and cocaine. A Mediterranean-type diet and, in patients with hypertension, reducing sodium intake is recommended. Exercise plans should take any mobility considerations into account. Alcohol consumption should be no greater than two drinks per day for men or one drink per day for women.[8]

Hemorrhagic Stroke

SAH often arises from a ruptured intracranial aneurysm or AVM and intervention as early as possible with either surgical clipping or endovascular coiling of the vascular anomaly reduces the risk of rebleeding and improves mortality.[6] For patients with cerebellar ICH and neurologic deterioration, brainstem compression, and/or hydrocephalus from ventricular obstruction, early surgical intervention and hematoma removal is recommended. For patients with cerebral ICH, the usefulness of surgical hematoma evacuation or use of minimally-invasive clot evacuation are not well established. Ventricular drainage with an extraventricular drain (EVD) is reasonable in patients with hydrocephalus causing decreased consciousness.[6]

Temperature Management

Fever worsens outcomes in patients with both hemorrhagic and ischemic stroke types. Identification of the source of fever and management is recommended to maintain patients within normothermia ranges. Pharmacologic and nonpharmacologic interventions can be considered and applied. Data are limited to support induced hypothermia; it should be done only in a controlled, clinical trial setting.[6,7]

Pharmacologic Therapy

Ischemic Stroke

Acute Treatment

The stroke council of the ASA has created and published guidelines that address the management of acute ischemic stroke.[7] For acute treatment, the only two pharmacologic agents with class I recommendations are alteplase initiated within 4.5 hours of stroke onset and aspirin started within 24 to 48 hours of stroke onset (Table 39-3).[7]

TABLE 39-3

Recommendations for Pharmacotherapy of Ischemic Stroke

Acute Treatment of Ischemic Stroke[7]		
Recommendation	**Class (Strength) of Recommendation[a]**	**Level (Quality) of Evidence[b]**
Alteplase 0.9 mg/kg IV (maximum 90 mg), 10% as a bolus with the remainder given over 1 hour in selected patients		
• Within 3 hours of onset	I	A
• Between 3 and 4.5 hours of onset	I	B-R
Tenecteplase 0.25 mg/kg IV bolus (maximum 25 mg) may be a reasonable alternative to alteplase for patients who are also eligible to undergo mechanical thrombectomy	IIb	B-R
Tenecteplase 0.4 mg/kg IV bolus (maximum 40 mg) has not been proved to be superior or non-inferior to alteplase but may be considered as an alternative to alteplase in patients with minor neurological impairment and no major intracranial occlusion	IIb	B-R
Aspirin 160-325 mg daily started within 48 hours of onset	I	A
Aspirin 81 mg daily and clopidogrel 75 mg daily for 21 days may be effective in reducing recurrent stroke in patients who do not receive IV alteplase and present with minor, non-cardioembolic stroke (NIHSS ≤ 3)	I	A
Ticagrelor is not recommended over aspirin for treatment of patients with minor acute stroke	III	B-R

Acute Treatment of Spontaneous Intracerebral Hemorrhage[6]			
Patients with a severe coagulation factor deficiency or severe thrombocytopenia should receive appropriate factor replacement therapy or platelets		I	C
Prophylactic antiseizure medication is not recommended		III	B
Secondary Prevention of Ischemic Stroke			
Stroke Etiology	**Recommendation**	**Class (Strength) of Recommendation[a]**	**Level (Quality) of Evidence[b]**
Noncardioembolic	Antiplatelet therapy[7]		
	- Aspirin 50-325 mg daily	I	A
	- Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily	I	A
	- Clopidogrel 75 mg daily	I	A
Cardioembolic (especially atrial fibrillation)	Anticoagulant therapy[7]		
	- Vitamin K antagonist (warfarin) (INR = 2-3)	I	A
	- Apixaban 5 mg twice daily	I	A
	- Dabigatran 150 mg twice daily	I	A
	- Edoxaban 60 mg daily	I	A
	- Rivaroxaban 20 mg daily	I	A
Atrial fibrillation without moderate to severe mitral stenosis or a mechanical heart valve	Apixaban, dabigatran, endoxaban, or rivaroxaban is preferred over warfarin	I	B-R
Risk Factor	**Recommendation[10]**	**Class (Strength) of Recommendation[a]**	**Level (Quality) of Evidence[b]**
LDL cholesterol > 100 mg/dL (2.59 mmol/L) with no known coronary heart disease, and no major cardiac sources of embolism	Atorvastatin 80 mg daily	I	A

Patients with atherosclerotic disease	Statins and ezetimibe, if needed; goal LDL cholesterol <70 mg/dL (1.81 mmol/L)	I	A
Very high risk (stroke + another major ASCVD or stroke + multiple high-risk conditions)[c] already taking statins at maximally tolerated dose and ezetimibe, but who still have LDL-cholesterol >70 mg/dL (1.81 mmol/L)	Proprotein convertase subtilisin/kexin type 9 inhibitor therapy	IIa	B-NR
Fasting triglycerides 135-499 mg/dL (1.53 - 5.64 mmol/L) and LDL cholesterol 41-100 mg/dL (1.06-2.59 mmol/L) who are on moderate- or high-intensity statin therapy, with HbA1c <10% (86 mmol/mol), and no history of pancreatitis, atrial fibrillation, or severe heart failure	Icoaspent ethyl 2 g twice daily	IIa	B-R
Fasting triglycerides ≥ 500 mg/dL (5.65 mmol/L)	Identify and address causes of hypertriglyceridemia; implement a very low-fat diet, avoid refined carbohydrates and alcohol; omega-3 fatty acids; fibrate therapy, if needed to prevent acute pancreatitis	IIa	B-NR
BP >130/80	BP reduction, goal <130/80 mm Hg	I	B-R
Patients who smoke	Smoking cessation with or without drug therapy	I	A
Men who drink > 2 alcoholic drinks per day or women who drink > 1 alcoholic drink per day	Reduce or eliminate alcohol consumption	I	B-NR
Patients who use stimulants and patients with infective endocarditis in the context of intravenous drug use	Cessation of use of substance	I	C-EO
Diabetes - treatment goal	Goal HbA1c ≤7% (53 mmol/mol)	I	A
Diabetes - drug therapy selection	Treatment with glucose-lowering agents with proven cardiovascular benefit (metformin + GLP1 receptor agonist therapy or sodium-glucose cotransporter 2 inhibitor) regardless of baseline HbA1C	I	B-R
Prediabetes, particularly with BMI ≥35 kg/m^2, <60 years, women with a history of gestational diabetes	Metformin 850 mg twice daily	IIb	B-R

[a] Class (strength) of recommendation : I, strong; IIa, moderate; IIb, weak; III, no benefit (moderate); 3, harm (strong).

[b] Level (quality) of evidence: A, high-quality evidence from more than 1 randomized clinical trial, meta-analyses of high-quality randomized clinical trials, or one or more randomized clinical trials corroborated by high-quality registry studies; B-R (randomized), moderate-quality evidence from one or more randomized clinical trials or meta-analyses of moderate-quality randomized clinical trials; B-NR (nonrandomized), moderate-quality evidence from one or more well-designed, well-executed nonrandomized studies, observational studies, or registry studies or meta-analyses of such studies; C-LD (limited data), randomized or nonrandomized observational or registry studies with limitations or design or execution, meta-analyses of such studies, or physiological or mechanistic studies in human subjects; C-EO (expert opinion), consensus of expert opinion based on clinical experience.

[c]Very high risk of future ASCVD events includes a history of multiple major ASCVD events or 1 major ASCVD event and multiple high-risk conditions. Major ASCVD events are history of ischemic stroke, acute coronary syndrome within the past 12 months, history of myocardial infarction, symptomatic peripheral arterial disease. High-risk conditions include: age ≥65 years; heterozygous familial hypercholesterolemia; history of coronary artery bypass surgery or percutaneous coronary intervention outside of the major ASCVD events; diabetes; hypertension; chronic kidney disease; current smoking.

ASCVD, atherosclerotic cardiovascular disease; BMI, body mass index; GLP1, glucagon-like peptide 1; HbA1c, hemoglobin A1c; ICH, intracerebral hemorrhage; INR, international normalized ratio; IV, intravenous; LDL, low-density lipoprotein; NIHSS, National Institutes of Health Stroke Scale.

Alteplase

⑥ Early pharmacologic reperfusion (initiated less than 4.5 hours from symptom onset) with IV alteplase has been a mainstay of acute pharmacologic treatment to improve functional ability after ischemic stroke as compared to no intervention.[7] Alteplase, or recombinant tissue plasminogen activator (rt-PA), is a fibrinolytic agent that exhibits a moderate binding preference for fibrin and facilitates the conversion of plasminogen to plasmin, leading to degradation of fibrin clots. Alteplase has a short half-life (approximately 4 minutes). The total dose for acute ischemic stroke is 0.9 mg/kg (maximum 90 mg), 10% administered as an intravenous (IV) bolus over 1 minute, and the remaining 90% given as an IV infusion over 60 minutes.[7]

The first large trial demonstrating the effectiveness of IV alteplase in the treatment of ischemic stroke was published in 1995. A subsequent study demonstrated improved functional outcome at 3 months in patients with acute ischemic stroke treated with alteplase between 3 and 4.5 hours of stroke symptom onset when compared with placebo (52.4% vs 45.2%).[7] Based on these data, the AHA/ASA guidelines extended the window for alteplase from 3 hours to up to 4.5 hours from symptom onset. However, there may be diminished benefit of alteplase in patients presenting within 3 to 4.5 hours from symptom onset and severe stroke (NIHSS>25 or evidence of more than one-third of MCA territory infarct on initial imaging).[7] Consequently, delays in alteplase therapy should be minimized and early administration prioritized since this approach is associated with improved outcomes.

Alteplase use is associated with a high risk for bleeding, including ICH. Therefore, adherence to the guideline-recommended protocol is essential for achieving a positive outcome and minimizing the risk. This protocol can be summarized as (a) stroke team activation, (b) brain imaging study (eg, CT scan), (c) treatment as early as possible within 4.5 hours of symptom onset, (d) meeting inclusion and exclusion criteria (TABLE 39-4), (e) administration of alteplase 0.9 mg/kg total dose (maximum dose of 90 mg), 10% given as a bolus over 1 minute and the remaining 90% given as an IV infusion over 1 hour, (f) avoidance of antithrombotic therapy (anticoagulant or antiplatelet) for 24 hours after alteplase, and (g) close patient monitoring for BP, neurologic status, and hemorrhage. Endovascular intervention is not a contraindication to alteplase and patients eligible for alteplase should receive pharmacologic treatment in addition to mechanical thrombectomy.[7]

TABLE 39-4

Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke

Inclusion Criteria

- Age ≥18 years
- Clinical diagnosis of ischemic stroke with neurologic deficit
- Time of symptom onset well established to be <4.5 hours from treatment initiation

Contraindications

- History of intracranial hemorrhageHistory of ischemic stroke within prior 3 monthsSymptoms/Imaging consistent with subarachnoid hemorrhage or acute intracerebral hemorrhage
- Current use of direct thrombin inhibitors or direct factor Xa inhibitors in prior 48 hours
- Use of treatment-dose low molecular weight heparin in prior 24 hours
- Infective endocarditis
- Intra-axial, intracranial neoplasm
- Aortic arch dissection
- Active internal bleeding or coagulopathy (platelets <100,000/mm^3 [100 × 10^9/L], INR>1.7, aPTT>40s, PT>15s)
- Severe head trauma in prior 3 months
- Gastrointestinal malignancy or bleeding within prior 21 days

Warnings/Use Clinical Judgment

- Unruptured/unsecured AVM or aneurysm >10 mm
- Major surgery or nonhead trauma
- History of bleeding diathesis
- Extensive regions of clear hypoattenuation on initial CT scan

aPTT, activated partial thromboplastin time; AVM, arteriovenous malformation; CT, computed tomography; INR, international normalized ratio; PT; prothrombin time.

Data from Reference 7.

Tenecteplase

Tenecteplase is a modified form of tissue plasminogen activator with protein substitutions that yield a higher degree of fibrin specificity and a longer half-life than alteplase. Unlike alteplase, tenecteplase can be administered as a single, rapid IV bolus dose. While tenecteplase is FDA-approved for the management of patients with acute ST-elevation myocardial infarction, use for ischemic stroke remains off-label. Tenecteplase has been studied in a variety of acute ischemic stroke populations and is specifically mentioned in the 2019 update to the AHA/ASA guidelines. Tenecteplase 0.4 mg/kg (maximum 40 mg), given as an IV bolus, may be considered as an alternative to alteplase for patients with ischemic stroke and mild neurologic impairment (class IIb recommendation).[7] It may also be reasonable to choose an IV bolus of tenecteplase 0.25 mg/kg (maximum 25 mg) over alteplase for patients who are also eligible to undergo mechanical thrombectomy (class IIb recommendation).[7] Ongoing studies may further define the role of tenecteplase in patients with acute ischemic, identify the optimal dose, and support stronger recommendations in the future.

Aspirin

Early aspirin therapy, within 24 to 48 hours from symptom onset, should be given to patients with acute ischemic stroke in the absence of aspirin allergy or other contraindications. For patients receiving alteplase, aspirin and other antithrombotics are generally held for 24 hours after alteplase administration to reduce the risk of hemorrhage.[7]

Early use of aspirin in ischemic stroke patients is recommended by the AHA/ASA guidelines to reduce the long-term risk of death and disability.[7] Data are limited to describe acute use of non-aspirin antiplatelet agents in the acute stroke phase, apart from combination therapy regimens described below. However, using an alternative antiplatelet agent in patients with acute ischemic stroke who have a severe allergy or contraindication to aspirin may be reasonable.[7]

Aspirin exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase (COX)-1, which, in platelets, prevents the conversion of arachidonic acid to thromboxane A2 (TXA2), a powerful vasoconstrictor and stimulator of platelet aggregation. The onset of the antiplatelet effect of aspirin is less than 60 minutes, and platelets remain impaired for their life span (5-7 days) after exposure to aspirin.[11] Aspirin also inhibits COX-2 in a dose-dependent manner, leading to decreased prostacyclin (PGI2) activity in vascular smooth muscle.[12] There is probably a point at which lower doses of aspirin do not completely block TXA2, and studies indicate that the lowest effective dose may be in the range of 75 mg/day.[12] Upper gastrointestinal (GI) discomfort and bleeding are the most common adverse effects of aspirin and have been shown to be dose-related. The risk of major bleeding is 43% higher in patients treated with aspirin compared to patients not receiving aspirin. The risk of bleeding is dose-dependent and increases with increasing age; therefore, the upper limit of the aspirin dose is between 300 mg and 325 mg.[7]

Some patients either have or develop high on-treatment platelet reactivity ("aspirin resistance") and can require higher doses or twice daily dosing to achieve the desired antiplatelet effect.[13] Several factors contribute to this effect, including aging, diabetes, hyperlipidemia, smoking, chronic kidney disease, and drug-drug interactions (eg, non-steroidal anti-inflammatory drugs).[14] Genetic polymorphisms, including those influencing activity of COX-1, COX-2, glycoprotein IIb/IIIa receptors, and adenosine diphosphate (ADP) receptors, may contribute to aspirin resistance.[15] Despite the growing evidence linking aspirin resistance to worse outcomes in patients with stroke, routine testing for aspirin resistance is not recommended.

Blood Pressure Management

In general, patients with acute ischemic stroke commonly present with elevated or normal BP. However, hypotension and hypovolemia, if present, should be corrected to maintain systemic perfusion and end organ function. For patients with elevated BP who are otherwise eligible for alteplase, the treatment of hypertension to a goal SBP of less than 185 mm Hg and diastolic BP of less than 110 mm Hg is recommended before thrombolytic administration. While data are limited, it is also reasonable to maintain blood pressure less than 185/110 mm Hg for patients undergoing mechanical thrombectomy. For patients not requiring IV thrombolytic therapy or endovascular intervention, "permissive hypertension", allowing BP to rise as high as 220/120 mm Hg for the first 48 to 72 hours, is often implemented as early initiation of antihypertensive therapy does not prevent death or dependency. For patients with comorbid conditions requiring BP lowering, a reduction of 15% is reasonable. See Table 39-3 for a summary of these recommendations and pharmacotherapeutic options.[7] When treating hypertension in acute ischemic stroke, it is typical to use IV drugs with a faster time to onset and ability to titrate to patient response. Calcium channel blocker infusions, such as nicardipine and clevidipine, are often preferred. Labetalol can be administered as an IV bolus dose or as a continuous infusion. In patients with refractory hypertension, there may be a role for last-line agents such as sodium nitroprusside to achieve BP goals.

Therapeutic Anticoagulation

Use of therapeutic anticoagulation (eg, unfractionated heparin or low-molecular-weight heparin) is not routinely recommended in the early phase of acute ischemic stroke treatment. The clinical benefit of therapeutic anticoagulation in the setting of nonocclusive intraluminal thrombus in acute stroke is limited. Restricted use on a case-by-case basis or in a clinical trial setting may be considered. Anticoagulation for non-stroke indications (eg, venous thromboembolism prophylaxis or treatment) must be weighed against the risk of ICH conversion in patients with acute ischemic stroke.[7] Patients with immobility after stroke should be receive either mechanical or pharmacologic venous thromboembolism prophylaxis. Drug selection, dosing, and timing of pharmacologic venous thromboembolism prophylaxis will depend on patient factors and conconimitant treatment for stroke.

Secondary Prevention

⑦ Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke and should be used in noncardioembolic strokes. Aspirin, extended-release dipyridamole plus aspirin, clopidogrel, and ticagrelor are all recommended for secondary stroke prevention.[4] In patients with atrial fibrillation, oral anticoagulation with apixaban, dabigatran, edoxaban, rivaroxaban, or warfarin is recommended for secondary stroke prevention.[4] Other pharmacotherapy recommended for secondary prevention of stroke includes treatment of hypertension and statin therapy. Current recommendations regarding the acute treatment and secondary prevention of stroke are given in Table 39-2.

Antiplatelet Agents

All patients who have had an acute ischemic stroke or TIA should receive long-term antithrombotic therapy for secondary prevention.[4] In patients with noncardioembolic stroke, this will be some form of antiplatelet therapy. In a comprehensive meta-analysis, antiplatelet therapy reduced the odds of a second stroke by 16% to 41% in patients with previous stroke.[16] While aspirin is the antiplatelet agent with the most data supporting its use, there is also evidence to support using clopidogrel and the combination product extended-release dipyridamole plus aspirin as alternative first-line agents for secondary stroke prevention.[8] For patients already taking aspirin at the time of a noncardioemoblic ischemic stroke or TIA, there is no evidence that increasing the dose of aspirin is more effective at preventing additional strokes.[8]

Clopidogrel

Clopidogrel exerts its antiplatelet effect by inhibiting the ADP pathway of platelet aggregation through antagonism of the purinergic receptor P2Y, G-protein coupled 12 ($P2Y_{12}$) receptor.[12,17] This effect causes an alteration of the platelet membrane and interference with the membrane–fibrinogenic interaction leading to a blocking of the platelet glycoprotein IIb/IIIa receptor. In the absence of a loading dose, the maximal antiplatelet effect is delayed for 3 to 7 days.

Clopidogrel is a prodrug and requires activation by the cytochrome P450 isoenzyme 2C19 (CYP2C19) to achieve its antiplatelet effect. There are polymorphisms of various alleles encoding for this enzyme, with *1 being the wild type, *17 leading to increased metabolism, and *2 and *3 causing decreased metabolism. Thus, individuals with one copy of *2 or *3 are classified as intermediate metabolizers and those with two copies of *2 or *3 or one copy of each (*2/*3) are termed poor metabolizers, leading to diminished antiplatelet activity.[18] Poor metabolizers are found in about 2% of Caucasians, 4% of African Americans, and 14% of Chinese.[18] Consequently, the Clinical Pharmacogenetics Implementation Consortium and the Dutch Pharmacogenetics Working Group of the Royal Dutch Association for the Advancement of Pharmacy both suggest pharmacogenetic testing prior to using clopidogrel.[18] However, current AHA/ASA guidelines for acute treatment of stroke do not suggest doing so.[8] Medications that inhibit CYP2C19 may also reduce the antiplatelet activity of clopidogrel. Omeprazole and esomeprazole both inhibit CYP2C19 and their use should be avoided in patients taking clopidogrel. Opioids slow gastric emptying, delaying and decreasing absorption, leading to reduced antiplatelet activity and, potentially, decreased efficacy.[19]

In a study of patients with atherothrombotic disorders (eg, ischemic stroke, myocardial infarction, or peripheral arterial disease), clopidogrel was slightly more effective than aspirin in preventing vascular events and had a similar incidence of adverse effects.[20] The tolerability of clopidogrel 75 mg/day is at least as good as medium-dose (325 mg/day) aspirin and there is less GI bleeding.[20] Clopidogrel is associated with an increased risk of diarrhea and rash, but discontinuation rates due to adverse effects are similar to those with aspirin 325 mg/day (5.3% and 6%, respectively).[20]

Extended-Release Dipyridamole Plus Aspirin

Dipyridamole, in high doses, is thought to inhibit phosphodiesterase, increasing intracellular cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), leading to inhibition of platelet activation.[12] Early studies of the role of dipyridamole in stroke prevention failed to show a benefit over aspirin alone. However, 25% of the patients who received combination dipyridamole and aspirin discontinued the therapy early, many due to adverse drug reactions. The discontinuation due to headache was more than threefold higher (10%) than the aspirin-alone group (3%).[21] Another study demonstrated similar efficacy in preventing recurrent stroke between the combination of extended-release dipyridamole and aspirin and clopidogrel.[22] However, clopidogrel was better tolerated with less bleeding and headache. Despite carefully educating and coaching patients on managing headache, discontinuation due to headache was six times higher in the extended-release dipyridamole plus aspirin group (5.9% vs 0.9%) compared to clopidogrel.[22] The extended-release formulation of dipyridamole is important in that it allows twice-daily administration. The use of immediate-release dipyridamole in combination with regular aspirin, in order to reduce costs, is unproven and should be discouraged.

Ticagrelor

Ticagrelor is a direct-acting $P2Y_{12}$ receptor inhibitor.[17] Ticagrelor (loading dose of 180 mg then 90 mg twice daily for 90 days) was compared to aspirin (300 mg loading dose then 100 mg daily 90 days) in a large clinical trial of patients with noncardioembolic stroke not treated with alteplase.[23] Ticagrelor did not demonstrate superiority to aspirin in this trial.[23] However, in a subgroup analysis of patients with an atherosclerotic cause of stroke, there was a 32% lower risk of secondary stroke within 90 days in patients treated with ticagrelor.[24] Despite this subgroup analysis, ticagrelor is not FDA-approved for secondary stroke prevention.

Dual Antiplatelet Therapy

The combination of two or more antiplatelet medications for secondary stroke prevention may be an option for select patients (Table 39-5). The combination of clopidogrel and aspirin has been the most studied dual antiplatelet strategy. A systematic review determined that short-term use of dual antiplatelet therapy (≤90 days) was associated with a significantly lower risk of recurrent stroke without an accompanying risk of major bleeding.[25] However, in longer-term studies (>90 days), the dual therapy was not associated with a reduced number of strokes but did increase the risk of major bleeding. Therefore, use of dual antiplatelet therapy with aspirin and clopidogrel for longer than 90 days is not recommended.[8]

TABLE 39-5

Dual Antiplatelet Recommendations for Patients with Noncardioembolic Ischemic Stroke or TIA

Patient Sub-type	Recommendation	Class (Strength) of Recommendation[a]	Level (Quality) of Evidence[b]
Minor stroke (NIHSS score ≤3)orhigh-risk TIA (ABCD2 score ≥4)[c]	Aspirin and clopidogrel should be initiated within 7 days (ideally within 12-24 hours). Continue for 21-90 days followed by single agent antiplatelet therapy	I	A
Recent (<30 days) minor stroke or TIA attributable to 70-99% stenosis of a major intracranial artery	Aspirin and clopidogrel 75 mg daily for up to 90 days followed by single agent antiplatelet therapy	IIa	B-NR
Recent (within 24 hours) minor stroke or high-risk TIA and concomitant ipsilateral >30% stenosis of a major intracranial artery	Ticagrelor 90 mg twice a day may be added to aspirin for up to 30 days	IIb	B-NR

[a] Class (strength) of recommendation : I, strong; IIa, moderate; IIb, weak; III, no benefit (moderate); III, harm (strong).

[b] Level (quality) of evidence: A, high-quality evidence from more than 1 randomized clinical trial, meta-analyses of high-quality randomized clinical trials, or one or more randomized clinical trials corroborated by high-quality registry studies; B-R (randomized), moderate-quality evidence from one or more randomized clinical trials or meta-analyses of moderate-quality randomized clinical trials; B-NR (nonrandomized), moderate-quality evidence from one or more well-designed, well-executed nonrandomized studies, observational studies, or registry studies or meta-analyses of such studies; C-LD (limited data), randomized or nonrandomized observational or registry studies with limitations or design or execution, meta-analyses of such studies, or physiological or mechanistic studies in human subjects; C-EO (expert opinion), consensus of expert opinion based on clinical experience.

[c] The ABCD2 score is a clinical prediction rule used to determine the risk for stroke soon after a TIA. Score 1 point each for age ≥60 years, blood pressure ≥140/90 mm Hg, speech disturbance, unilateral weakness, 10-59 minute duration, diabetes and 2 points for duration ≥ 60 minutes.

NIHSS, National Institutes of Health Stroke Scale; TIA, transient ischemic attack.

Data from Reference 8.

Ticagrelor (180 mg loading dose then 90 mg twice daily for 30 days) in combination with aspirin (300-325 mg loading dose then 75-100 mg daily) has been compared to aspirin alone in patients with mild-moderate noncardioembolic stroke.[26] Fewer patients in the dual therapy group had stroke or death in the first 30 days compared to the aspirin-only group. However, the overall level of disability was not different between the groups, and the incidence of severe bleeding, including ICH, was increased in the dual therapy group. A subgroup analysis of patients at higher risk for recurrent stroke found rates of stroke and death were lower in the combination therapy group compared to aspirin alone while no difference in severe bleeding was observed between the groups.[27] Consequently, that the use of ticagrelor and aspirin together for secondary stroke prevention is only recommended for patients with minor stroke or TIA with more than 30% stenosis of an ipsilateral major intercranial artery; combination therapy should be limited to a duration of 30 days.[8]

The positive results of dual antiplatelet therapy led researchers to investigate triple antiplatelet therapy. One trial compared the combination of aspirin, sustained-release dipyridamole, and clopidogrel to a "guideline group" which received either clopidogrel or aspirin and sustained-release dipyridamole. This trial was stopped early because of a doubling of the risk of major bleeding in the triple therapy group. There was no difference in risk of recurrent stroke between the groups.[28] Therefore, the use of triple antiplatelet therapy is not recommended.[8]

Oral Anticoagulants

⑧ Oral anticoagulation is the treatment of choice for the prevention of stroke in patients with atrial fibrillation and atrial flutter.[4,29] Patients with atrial fibrillation and a recent history of stroke or TIA are among the highest risk groups for stroke recurrence. However, there is a significant risk of bleeding with anticoagulation. Thus, a stroke risk stratification tool known as CHA_2DS_2-VASc has been developed to determine the patient's risk of stroke (see Chapter 40 "The Arrhythmias"). CHA_2DS_2-VASc scores greater than zero should receive oral anticoagulation therapy.[4] Several risk stratification tools have been developed to evaluate bleeding and determine bleeding risk. HAS-BLED is a simple tool that is widely used.[30] A HAS-BLED score >2 indicates a high risk for bleeding and should be accompanied by more intensive patient monitoring (Table 39-6).

TABLE 39-6

HAS-BLED Score for Assessing Bleeding Risk with Oral Anticoagulants

HAS-BLED Symbol	Risk Factor	Score
H	**H**ypertension (SBP > 160 mm Hg)	1
A	**A**bnormal renal or liver function	1
S	Prior **S**troke	1
B	Prior major **B**leeding or **B**leeding predisposition	1
L	**L**abile INRs (in therapeutic range < 60% of time)	1
E	**E**lderly (age > 65 years)	1
D	**D**rugs of abuse or excessive alcohol use	1

HAS-BLED score > 2 associated with clinically relevant and major bleeding.

SBP, systolic blood pressure, INR, international normalized ratio.

Data from References 4,30.

In patients with atrial fibrillation, adjusted-dose warfarin reduces stroke risk by 62% when compared to placebo and by 36% when compared to aspirin.[31] When using warfarin, targeting an international normalized ratio (INR) of 2 to 3 prevents stroke with the lowest bleeding risk; therefore, a target INR of 2 to 3 is recommended for the secondary prevention of stroke.[4,7,29] In settings of atrial fibrillation with mechanical heart valves or moderate to severe mitral stenosis, warfarin should be used.[8]

Direct-acting oral anticoagulants (DOAC), including direct thrombin inhibitors (dabigatran) and direct factor Xa inhibitors (rivaroxaban, edoxaban, and apixaban), have significant advantages over warfarin in terms of ease of dosing and less food and drug interactions. In addition, all four agents have been shown to be as effective, and in some cases, superior to warfarin in reducing stroke risk with reduced rates of serious hemorrhage.[29]

Before using a DOAC, the patient's renal function must be evaluated and the dose adjusted if significant renal impairment is present (TABLE 39-7).

Patients with creatinine clearance less than 15 mL/min (0.25 mL/s) or who require hemodialysis, either warfarin or apixaban are preferred.[29] Additionally, edoxaban should not be given to patients with creatinine clearances above 95 mL/min because the risk of stroke is increased compared to warfarin.[29] There is limited information on the use of these agents in patients with a body mass index over 40 kg/m^2.[32] However, emerging data suggest that apixaban and rivaroxaban may be the best options for patients with a body weight over 120 kg or body mass index over 40 kg/m^2.[33]

TABLE 39-7

Direct-acting Oral Anticoagulant Dosing Adjustments Required for Renal Impairment.

Direct-acting Oral Anticoagulant	Usual Oral Dosing for Stroke Prevention in Atrial Fibrillation	Dosing Adjustments
Apixaban	5 mg twice daily	2.5 mg twice daily in patients with at least 2 high-risk characteristics below:Age ≥ 80 yearsBody weight ≤ 60 kgSerum creatinine ≥ 1.5 mg/dL (133 μmol/L)
Dabigatran	150 mg twice daily	75 mg orally twice daily if creatinine clearance 15-30 mL/min (0.25-0.50 mL/s)
Edoxaban	60 mg daily	30 mg orally daily if creatinine clearance is 15-50 mL/min (0.25-0.83 mL/s)
Rivaroxaban	20 mg daily with food	15 mg orally daily with evening meal if creatinine clearance is ≤50 mL/min (0.83 mL/s)

The timing of oral anticoagulant initiation has been in question due to the risk of hemorrhagic conversion of the infarcted area. Guidelines suggest for patients with a low risk of hemorrhagic conversion, anticoagulation can begin 2 to 14 days after the stroke. However, in patients with a high risk of hemorrhagic conversion, waiting at least 14 days is recommended.[8]

Blood Pressure Management

⑨ Elevated BP is very common in ischemic stroke patients, and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.[8] Current guidelines have the following recommendations for BP control after ischemic stroke to prevent future strokes:

- Adults with previously treated hypertension who experience a stroke or TIA should be restarted on antihypertensive treatment after the first few days of the index event to reduce the risk of recurrent stroke and other vascular events.
- For adults with hypertension who experience a stroke or TIA, treatment with a thiazide diuretic, angiotensin-converting enzyme (ACE) inhibitor, or angiotensin II receptor blocker is useful.
- Adults not previously treated for hypertension who experience a stroke or TIA and have an average BP of 130/80 mm Hg or higher should be prescribed antihypertensive treatment a few days after the index event to reduce the risk of recurrent stroke and other vascular events.
- For adults who experience a stroke or TIA, a BP goal of less than 130/80 mm Hg is recommended.[8,34]

Cholesterol Management

⑩ The statins have been shown to reduce the risk of stroke by approximately 30% in patients with coronary artery disease and elevated plasma lipids.[8] Patients with ischemic stroke without known heart disease but who have LDL cholesterol over 100 mg/dL (2.59 mmol/L) should be given atorvastatin 80 mg daily to reduce the risk of stroke recurrence.[8] Patients with ischemic stroke or TIA who have atherosclerotic cardiovascular disease (ASCVD) should be given lipid-lowering therapy with a high-intensity statin (and ezetimibe, if necessary) to reach a goal of LDL cholesterol of less than 70 mg/dL (1.81 mmol/L).[8] In very high-risk patients (multiple major atherosclerotic cardiovascular events or one major atherosclerotic cardiovascular event and multiple high-risk conditions) who are taking maximally tolerated statins and ezetimibe with LDL cholesterol ≥70 mg/dL (1.81 mmol/L), a proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitor may be considered.[8]

Hypertriglyceridemia has recently been recognized as a risk factor for ASCVD but lowering triglycerides with extended-release niacin or fibrates has not been shown to change cardiovascular outcomes. In contrast, adding icosapent ethyl 2 g twice daily to statin therapy has been shown to reduce major adverse cardiovascular events, including stroke, in patients with fasting triglycerides of 135 to 499 mg/dL (1.53 to 5.64 mmol/L) and LDL cholesterol of 41 to 100 mg/dL (1.06 to 2.59 mmol/L).[35] Therefore, icosapent ethyl is recommended for these patients with provided they have HbA1c <10% (86 mmol/mol) and no history of pancreatitis, atrial fibrillation, or severe heart failure.[8] When patients have fasting triglycerides of 500 mg/dL (5.65 mmol/L) or more, non-pharmacologic efforts to reduce them should be initiated along with fibrate therapy, if needed.[8]

Hemorrhagic Stroke

Acute Treatment

The stroke council of the AHA/ASA has published guidelines on the management of spontaneous ICH in 2015.[6] While the usefulness of pharmacologic interventions is limited in this stroke type, the management of hypertension and reversal of coagulopathy in anticoagulant-associated ICH should be considered.

Blood Pressure Management

Hypertension in patients with hemorrhagic stroke increases the risk of hematoma expansion. For patients with ICH presenting with a SBP above 220 mm Hg, aggressive lowering of BP with continuous IV infusion medications is reasonable. Clinical trials have demonstrated that acute lowering of SBP to a goal of 140 mm Hg is safe and may be effective at improving functional outcomes.[6] For patients with SAH due to aneurysm rupture, targeting a SBP less than 160 mm Hg is reasonable in the time period from symptom onset to aneurysm obliteration.[6] Refer to Table 39-3 for a summary of these recommendations and pharmacologic treatment options.

Anticoagulation Reversal

When ICH occurs in a patient on anticoagulants, the use of reversal agents to correct the medication-induced coagulopathy should be considered. For patients on warfarin with elevated INR, reversal with vitamin K, typically IV, in combination with a four-factor prothrombin complex concentrate is recommended. Fresh frozen plasma can be used in place of a prothrombin complex concentrate, if necessary, but is not preferred.[6] Idarucizumab may be considered for reversing the effect of dabigatran specifically.[36] Factor Xa inhibitors, such as rivaroxaban and apixaban, may be reversed with andexanet alfa[37] (Table 39-8).

Table 39-8

Selected Anticoagulant Reversal

Drug	First-Line Reversal Recommendation	Alternate Treatment
Warfarin	Vitamin K 10 mg IV ×1 -and- 4-Factor Prothrombin Complex Concentrate (4PCC) INR 2 to <4: 25 units/kg, max 2,500 units INR 4-6: 35 units/kg, max 3,500 units INR >6: 50 units/kg, max 5,000 units	Vitamin K 10 mg IV ×1 -and- Fresh Frozen Plasma (FFP) 10-15 mL/kg
Dabigatran	Idarucizumab 5 gm IV ×1	Hemodialysis 4PCC 50 units/kg
Rivaroxaban ≤10 mg	Andexanet alfa 400 mg IV Bolus at rate of 30 mg/min, followed by 4 mg/min IV infusion up to 120 minutes	4PCC 50 units/kg
Rivaroxaban >10 mg or unknown dose	If <8 hours since last dose or unknown time andexanet alfa 800 mg IV bolus at rate of 30 mg/min, followed by 8 mg/min IV infusion up to 120 minutes If ≥8 hours since last dose Andexanet alfa 400 mg IV Bolus at rate of 30 mg/min, followed by 4 mg/min IV infusion up to 120 minutes	4PCC 50 units/kg
Apixaban ≤5 mg	Andexanet alfa 400 mg IV Bolus at rate of 30 mg/min, followed by 4 mg/min IV infusion up to 120 minutes	4PCC 50 units/kg
Apixaban >5 mg or unknown dose	If <8 hours since last dose or unknown time Andexanet alfa 800 mg IV bolus at rate of 30 mg/min, followed by 8 mg/min IV infusion up to 120 minutes If ≥8 hours since last dose Andexanet alfa 400 mg IV Bolus at rate of 30 mg/min, followed by 4 mg/min IV infusion up to 120 minutes	4PCC 50 units/kg
Edoxaban	Andexanet alfa not studied	4PCC 50 units/kg

FFP, fresh frozen plasma; IV, intravenous; 4PCC, 4-factor prothrombin complex concentrate; INR, international normalized ratio.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with acute stroke should be monitored intensely for the development of neurologic worsening (recurrence or extension of stroke), complications (venous thromboembolism or infection), and adverse effects from pharmacologic or nonpharmacologic interventions. The most common reasons for deterioration in a stroke patient are (a) extension of the original lesion—ischemic or hemorrhagic—in the brain, (b) development of cerebral edema and elevated intracranial pressure, (c) hypertensive emergency, (d) infection (urinary and respiratory most common), (e) venous thromboembolism (deep vein thrombosis and pulmonary embolism), (f) electrolyte abnormalities and cardiac rhythm disturbances (can be associated with brain injury), and (g) recurrent stroke.

The approach to monitoring drug therapy in the hospitalized stroke patient is summarized in Table 39-9. The plan should be customized for individual patients based on the etiology of the stroke, their comorbidities, and ongoing disease processes.

TABLE 39-9

Monitoring Stroke Therapy in Hospitalized Patients

Drug	Adverse Effect	Monitoring Parameters	Comments
Alteplase and tenecteplase	Bleeding	Neurologic examination, blood pressure	Every 15 minutes × 1 hour; every 30 minutes × 6 hours; every 1 hour × 17 hours; every shift after
Aspirin	Bleeding		Daily
Clopidogrel	Bleeding		Daily
Extended-release dipyridamole plus aspirin	Headache, bleeding		Daily
Ticagrelor	Bleeding, bradycardia, dyspnea	Heart rate, respiratory rate	Bleeding daily, heart rate and respiratory rate as clinically indicated
Direct-acting oral anticoagulants	Bleeding		Daily
Warfarin	Bleeding	PT/INR, hemoglobin, hematocrit	Daily

INR, international normalized ratio; PT, prothrombin time.

For survivors of noncardioembolic strokes, approximately 3% to 4% per year will experience another stroke. One-third to one-half of these strokes occur while patients are on antiplatelet therapy to prevent stroke.[38] None of these agents reduces stroke risk to zero; some of the most important causes of breakthrough strokes are nonadherence, inappropriate dosing, reduced absorption, increased metabolism, drug-drug interactions, and genetic polymorphisms.[38] The healthcare practitioner is in a position to impact several of these factors. Nonadherence can have a root cause in a lack of understanding of therapy, adverse effects of the therapy, or the number of medications on discharge, among other factors.

CONCLUSION

Treatment of stroke requires a team approach to provide an accurate diagnosis to guide treatment and select therapies proven to improve outcomes. Careful patient selection for pharmacologic and nonpharmacologic therapies is paramount. Monitoring treatment helps assure goals of therapy are met.

ABBREVIATIONS

ACE	angiotensin-converting enzyme
ADP	adenosine diphosphate
AHA	American Heart Association
aPTT	activated partial thromboplastin time

SELF-ASSESSMENT QUESTIONS

1. A cardioembolic stroke is a type of ______________ stroke.

   A. Hemorrhagic

   B. Ischemic

   C. Lacunar

   D. Cerebellar

2. Which of the following pairs correctly matches the type of hemorrhagic stroke to one of its potential causes?

   A. Intracerebral hemorrhage: the rupture of an intracerebral aneurysm

   B. Intracerebral hemorrhage: trauma

   C. Subarachnoid hemorrhage: the rupture of an arteriovenous malformation

   D. Subarachnoid hemorrhage: uncontrolled hypertension

3. RT is a 77-year-old man who presents to the emergency department with symptoms of an ischemic stroke. Past medical history includes hypertension, hypothyroidism, benign prostatic hypertrophy, and hypercholesterolemia. What are RT’s stroke risk factors?

   A. Age, hypertension, and hypercholesterolemia

   B. Age, sex, hypertension, hypothyroidism, and hypercholesterolemia

   C. Age, sex, hypertension, and hypercholesterolemia

   D. Sex, hypothyroidism, benign prostatic hypertrophy, and hypercholesterolemia

   E. Sex, hypertension, and hypercholesterolemia

4. Which of the following is *not* a symptom of an acute stroke?

   A. Inability to speak

   B. Loss of vision

   C. Weakness on one side of the body

   D. Whole body numbness

5. Who is the best candidate for carotid stenting to reduce recurrent stroke?

   A. A 65-year-old female with 50% stenosis of the ipsilateral internal carotid artery

   B. A 65-year-old male with 75% stenosis of the ipsilateral internal carotid artery

   C. A 75-year-old male with 50% stenosis of the ipsilateral internal carotid artery

   D. A 75-year-old female with 75% stenosis of the ipsilateral internal carotid artery

6. BN is an 84-year-old male who presents to the emergency department with acute ischemic stroke symptoms. Symptoms began 2 hours ago. Current blood pressure is 176/98 mm Hg and glucose is 110 mg/dL (6.1 mmol/L). A computed tomography (CT) scan of the head that shows no bleeding. The patient is currently taking aspirin 81 mg daily and lisinopril 10 mg daily. He has no medication allergies. Is BN a candidate for alteplase?

   A. Yes.

   B. No, his symptoms began too long ago.

   C. No, he is too old.

   D. No, he is taking aspirin.

7. KC is a 65-year-old woman who presents to the emergency department with acute ischemic stroke symptoms. Symptoms began 6 hours ago. Current blood pressure is 170/96 mm HG and her glucose is 104 mg/dL (5.8 mmol/L). A computed tomography (CT) scan of the head that shows no bleeding. The patient is currently taking hydrochlorothiazide 25 mg daily and is allergic to aspirin (oral facial edema). Is KC a candidate for alteplase?

   A. Yes.

   B. No, her symptoms began too long ago.

   C. No, she is too old.

   D. No, she is taking hydrochlorothiazide.

8. ST is a 68-year-old woman who presented with an ischemic stroke 2 days ago. The patient received alteplase and the neurological deficits improved. Prior to the stroke, the patient was taking no medications. The patient is allergic to aspirin (hives and shortness of breath). Which of the following agents should ST receive to prevent recurrent strokes?

   A. Aspirin

   B. Clopidogrel

   C. Clopidogrel plus aspirin

   D. Extended-release dipyridamole plus aspirin

9. FR is a 58-year-old man who has had atrial fibrillation for 5 years. The patient was maintained on aspirin 325 mg daily. Four days ago, the patient sustained an ischemic stroke. What is the best choice of therapy for FR to prevent recurrent stroke?

   A. Aspirin

   B. Clopidogrel

   C. Extended-release dipyridamole plus aspirin

   D. Rivaroxaban

10. JC is a 79-year-old 150 kg man who recently sustained an ischemic stroke. During the workup, the patient was found to have atrial fibrillation. Blood

pressure is 145/90 mm Hg. Serum creatinine is 4.5 mg/dL (398 μmol/L) (creatinine clearance 28 mL/min [0.47 mL/s]) and BMI is 50 kg/m^2. Which of the following oral anticoagulants is most appropriate for JC?

A. Apixaban 5 mg daily

B. Edoxaban 30 mg daily

C. Dabigatran 150 mg twice daily

D. Warfarin adjusted to a target INR of 2 to 3

11. What is the HAS-BLED score for JC from question 10?

A. 1

B. 2

C. 3

D. 4

12. RG is a 74-year-old man who is being discharged from the hospital after a mild stroke. Blood pressure has stabilized at 156/98 mm Hg. Low-density lipoprotein cholesterol is 110 mg/dL (2.84 mmol/L). On which of the following regimens should RG be placed?

A. Atorvastatin 40 mg daily

B. Hydrochlorothiazide 25 mg daily plus rosuvastatin 20 mg daily

C. Lisinopril 5 mg daily

D. Lovastatin 40 mg daily plus losartan 50 mg daily

13. Which of the following is an appropriate monitoring parameter for a patient given alteplase?

A. Bleeding

B. Blue discoloration of the skin

C. Headache

D. Tongue swelling

14. BC is a 58-year-old man with atrial fibrillation who sustained an ischemic stroke and was placed on warfarin. Which of the following is an appropriate monitoring plan for BC?

A. Check blood glucose daily

B. Check blood pressure three times daily

C. Monitor INR for a target of 2 to 3

D. Monitor tyramine-containing food consumption

15. MP is a 66-year-old woman who sustained an ischemic stroke and was discharged on clopidogrel 75 mg daily plus aspirin 81 mg daily for 21 days. Which of the following will help decrease the patient's chance of recurrent stroke?

A. Follow-up regarding adherence

B. Frequently monitoring her blood pressure

C. Frequently monitoring her weight

D. Screening for depression

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The two major types of stroke are ischemic and hemorrhagic. Ischemic strokes are often the result of large artery atherosclerosis, small artery disease, or cardioembolism. These three subtypes are the most common etiologies of ischemic strokes. See “Etiology” section for further description.

2. **C.** Subarachnoid hemorrhage occurs when blood enters the subarachnoid space, which can occur due to trauma, rupture of an intracerebral aneurysm, or rupture of an arteriovenous malformation. Intracerebral hemorrhage, however, occurs when bleeding occurs in the brain parenchyma itself, with the formation of a hematoma within the brain. Uncontrolled hypertension is the most common causative factor for intracerebral hemorrhage, but antithrombotic therapy, cerebral amyloid angiopathy, and some drugs of abuse are also associated with intracerebral hemorrhage. See “Etiology” section for further description.

3. **C.** The nonmodifiable stroke risk factors are age, race, sex, low birth weight, and genetic factors. The most common modifiable, well-documented risk factors for ischemic stroke include hypertension, cigarette smoking, diabetes, atrial fibrillation, and dyslipidemia. See “Risk Factors” section for a comprehensive review.

4. **D.** Symptoms of acute stroke include weakness on one side of the body, inability to speak, loss of vision, vertigo and/or falling and occasionally headache. Stroke symptoms tend to involve only one side of the body. See the Clinical Presentation box for a review of stroke presentation.

5. **B.** In patients younger than 70 years with 70% to 99% stenosis of an ipsilateral internal carotid artery, carotid stenting can be performed. See “Nonpharmacologic Therapy” section for more details.

6. **A.** This patient is within the 4.5-hour window for alteplase administration, his blood pressure is <180/110 mm Hg, and he has no intracranial bleeding. Patients can be maintained on aspirin and receive alteplase. Please see and Table 39-2 for blood pressure management and criteria for alteplase use in the setting of acute stroke.

7. **B.** This patient is not within the 4.5-hour window for alteplase administration. Please see Table 39-4 for criteria for alteplase use in the setting of acute stroke.

8. **B.** This patient is allergic to aspirin; thus, it should not be a component of her therapy. Please see “Antiplatelet Agents” section for further discussion of the antiplatelet agents.

9. **D.** Oral anticoagulation is the treatment of choice for the prevention of stroke in patients with atrial fibrillation. Choice of agent may include warfarin, dabigatran, rivaroxaban, edoxaban, and apixaban. Please see “Oral Anticoagulant” section for more details on choosing between these agents.

10. **D.** The direct-acting oral anticoagulant doses need to be adjusted for patients with renal dysfunction. There is limited information on the use of these agents in patients with a body mass index over 40 kg/m^2. Therefore, warfarin would be the better choice for this patient. See “Oral Anticoagulant” section for more details of dosing these agents in decreased renal functioning.

11. **B.** This patient would receive points for a history of stroke and his age (>65 years). See Table 39-7 for HAS-BLED scoring.

12. **B.** This patient will require blood pressure lowering because his blood pressure is >140/90 mm Hg. He will also require high-intensity statin therapy because he is less than 75 years old. See “Blood Pressure Management” and “Statins” sections for additional review of this topic.

13. **A.** It is appropriate to monitor bleeding in a patient given alteplase. See Table 39-9 for additional monitoring parameters for hospitalized patients with ischemic stroke.

14. **C.** Target INR for patients with atrial fibrillation who are given warfarin is 2.5. See Table 39-2.

15. **A.** Some of the most important causes of breakthrough strokes are nonadherence, inappropriate dosing, reduced absorption, increased metabolism, drug-drug interactions, and genetic polymorphisms. Monitoring blood pressure, weight, or mood are unlikely to decrease future strokes. See "Evaluation of Therapeutic Outcomes" section.

Chapter 40: Arrhythmias

Jessica J. Tilton; Stephen T. Phillips; Jerry L. Bauman

KEY CONCEPTS

KEY CONCEPTS

① The use of antiarrhythmic drugs (AADs) in the United States has declined because clinical trials have shown increased mortality with their use due to proarrhythmic adverse medication reactions and limited efficacy. AADs have been increasingly replaced by nonpharmacologic approaches such as ablation and the implantable cardioverter defibrillator (ICD). However, AADs remain a key tool in the management of many rhythm disorders.

② AADs frequently cause adverse medication reactions and are complex in their pharmacokinetic characteristics. Close monitoring is required of all of these medications to assess for adverse reactions as well as potential medication interactions.

③ The most commonly prescribed AAD is amiodarone, which is effective in terminating and preventing a wide variety of symptomatic supraventricular and ventricular arrhythmias. However, amiodarone is plagued by frequent adverse medication reactions and requires close monitoring. The most concerning toxicity is pulmonary fibrosis. The side effect profiles of the intravenous (IV) (acute, short-term) and oral (chronic, long-term) forms of amiodarone differ substantially.

④ In patients with atrial fibrillation (AF), therapy is traditionally aimed at controlling the ventricular rate, preventing thromboembolic (TE) complications, and restoring and maintaining sinus rhythm (SR). Traditionally, many have pointed to the AFFIRM trial that maintenance of SR was often not necessary. However, several recent studies challenge this idea, particularly for patients with heart failure with reduced ejection fraction (HFrEF). AADs are also useful in reducing early AF recurrence in the periprocedural period and may improve long-term post-ablation outcomes.

⑤ Paroxysmal supraventricular tachycardia (PSVT) is usually a result of either reentry (involving either the atrioventricular [AV] node or incorporating an accessory pathway) or ectopic atrial activity (atrial tachycardia). Common supraventricular tachycardias are often terminated acutely with AV nodal-blocking medications, such as adenosine. For most patients, catheter ablation effectively cures this arrhythmia.

⑥ Patients with Wolff-Parkinson-White (WPW) syndrome may have several different tachycardias that are acutely treated by different strategies: orthodromic reentry (adenosine), antidromic reentry (adenosine or procainamide), and AF (procainamide or ibutilide). AV nodal-blocking medications are contraindicated in patients with WPW syndrome and AF. The mainstay of long-term therapy for WPW remains catheter ablation.

⑦ AADs (except for β-blockers) should not be used routinely in patients with prior myocardial infarction (MI) or left ventricular (LV) dysfunction for the treatment of premature ventricular complexes (PVCs). More specifically, the routine suppression of asymptomatic PVCs with AADs is not recommended.

⑧ Patients with hemodynamically significant ventricular tachycardia (VT) or ventricular fibrillation (VF) not associated with an acute MI who are successfully resuscitated (with electrical cardioversion, epinephrine, amiodarone, and/or lidocaine) are at high risk for sudden cardiac death (SCD). In most cases, implantation of an ICD is recommended for “secondary prevention.” AADs can be useful to prevent recurrent ICD shocks, particularly when catheter ablation is not an option or has been unsuccessful.

⑨ Implantation of an ICD should be considered for the primary prevention of SCD in certain high-risk patient populations. High-risk patients include those with a history of MI and LV dysfunction (regardless of whether they have inducible sustained ventricular arrhythmias) as well as those with New York Heart Association (NYHA) class II or III HFrEF.

⑩ Life-threatening medication-induced ventricular proarrhythmia generally takes two forms: sinusoidal or incessant monomorphic VT (caused by class Ic AADs) and torsades de pointes (TdP) (caused by class Ia or III AADs and many other noncardiac medications).

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled "Normal Sinus Rhythm on an EKG" in Khan Academy (duration: 8:52) by Bianca Yoo. This video provides a brief overview of the cardiac conduction system and how it translates to an electrocardiogram. The video is useful to enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

The heart has two basic properties, namely, an electrical property and a mechanical property. The synchronous interaction between these two properties is complex, precise, and relatively enduring. The study of the electrical properties of the heart has grown at a steady rate, interrupted by periodic salvos of scientific breakthroughs. Einthoven's pioneering work allowed graphic electrical tracings of cardiac rhythm and probably represents the first of these breakthroughs. This discovery of the surface electrocardiogram (ECG) has remained the cornerstone of diagnostic tools for cardiac rhythm disturbances. Since then, intracardiac recordings and programmed cardiac stimulation have advanced our understanding of arrhythmias, and microelectrode, voltage clamping, and patch clamping techniques have allowed considerable insight into the electrophysiologic actions and mechanisms of antiarrhythmic drugs (AADs). The new era of molecular biology and mapping of the human genome promises even greater insights into mechanisms (and potential therapies) of arrhythmias. Noteworthy in this regard is the discovery of genetic abnormalities in the ion channels that control electrical repolarization (heritable long QT syndrome) or depolarization (Brugada syndrome).

① There was some expectation that advances in AAD discovery would lead to a highly effective and nontoxic agent that would be effective for a majority of patients. Instead, significant problems with medication toxicity and proarrhythmia (provoking a new arrhythmia or exacerbating a preexisting arrhythmia) have resulted in a decline in AAD usage in the United States since 1989. The other phenomenon that has significantly contributed to the decline in AAD use is the development of extremely effective nonpharmacologic therapies. Technical advances have made it possible to permanently interrupt reentry circuits with radiofrequency ablation, which renders long-term AAD use unnecessary in certain arrhythmias. Furthermore, the impressive survival data associated with the use of implantable cardioverter defibrillators (ICDs) for the primary and secondary prevention of SCD have led most clinicians to choose "device" therapy as the first-line treatment for patients who are at high risk for life-threatening ventricular arrhythmias. These nonpharmacologic therapies have become increasingly popular for the management of arrhythmias, avoiding the potential proarrhythmic effects and organ toxicities associated with AADs.

PATHOPHYSIOLOGY

Normal Conduction

Electrical activity is initiated by the sinoatrial (SA) node and moves through cardiac tissue through a specialized conduction system that rapidly propagates the electrical wavefront through the ventricular muscle (Fig. 40-1, panel A). The SA node initiates cardiac rhythm under normal circumstances because this tissue possesses the highest degree of automaticity or rate of spontaneous impulse generation at a rate of 60 to 100 beats/min. The degree of automaticity of the SA node is largely influenced by the autonomic nervous system in that both cholinergic and sympathetic innervations control the sinus rate (Fig. 40-1, panel C). Most tissues within the conduction system also possess varying degrees of inherent automatic properties. However, the rates of spontaneous impulse generation of these tissues are generally less than that of the SA node. Thus, these latent automatic pacemakers are continuously overdriven by impulses arising from the SA node (primary pacemaker) and do not become clinically apparent.

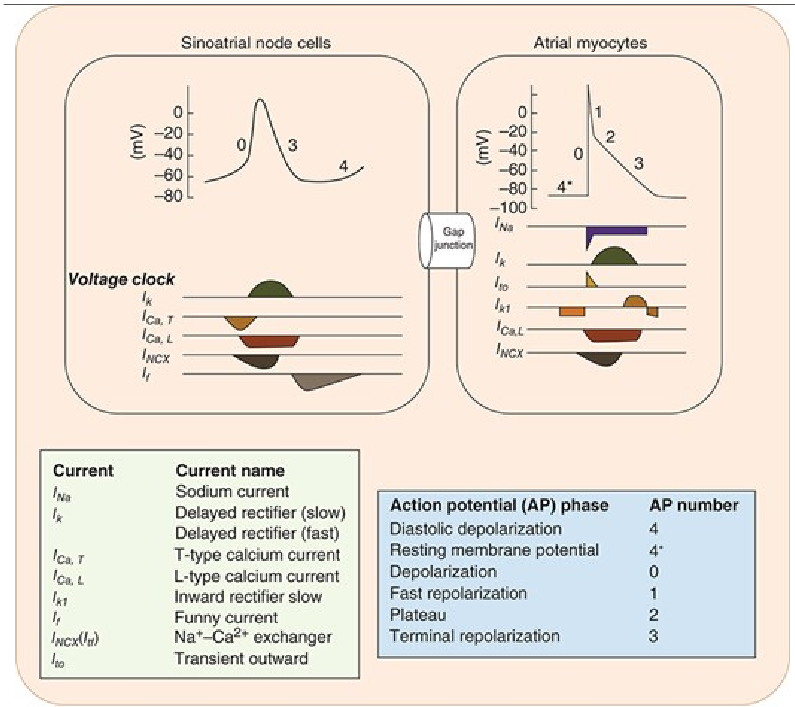
From the SA node, electrical activity moves in a wave front through a specialized atrial conducting system and eventually gains entrance to the ventricle via the AV node and a large bundle of conducting tissue referred to as the bundle of His. The AVN and bundle of His are largely influenced by autonomic input and possess a relatively high degree of inherent automaticity at about 40 beats/min. From the bundle of His, the cardiac conduction system bifurcates into several (usually three) bundle branches: one right bundle and two left bundles. These bundle branches further arborize into a conduction network referred to as the Purkinje system. The conduction system innervates the mechanical myocardium and serves to initiate excitation–contraction coupling and the contractile process in a precise and organized fashion. Following electrical stimulation, cells within the heart enter a brief period during which they cannot again be excited, referred to as the refractory period. As the electrical wave front moves down the conduction system, the impulse eventually encounters tissue refractory to stimulation (recently excited) and subsequently dies out. The SA node subsequently recovers, fires spontaneously, and begins the process again.

Prior to cellular excitation, an electrical gradient, referred to as the resting membrane potential (RMP), results from differences in ion concentrations inside and outside of the cell. At RMP, the cell is polarized primarily by the action of active membrane ion pumps, the most notable of these being the sodium–potassium pump. For example, this specific pump (in addition to other systems) attempts to maintain the intracellular sodium concentration at 5 to 15 mEq/L (mmol/L), the extracellular sodium concentration at 135 to 142 mEq/L (mmol/L), the intracellular potassium concentration at 135 to 140 mEq/L (mmol/L), and the extracellular potassium concentration at 3 to 5 mEq/L (mmol/L).

Electrical stimulation (or depolarization) of the cell will result in changes in membrane potential over time or a characteristic action potential (AP) curve (Fig. 40-2). The AP curve results from the transmembrane movement of specific ions and is divided into different phases. Phase 0 or initial, rapid depolarization of atrial and ventricular tissues is caused by an abrupt increase in the permeability of the membrane to sodium influx. This rapid depolarization more than equilibrates (overshoots) the electrical potential, resulting in a brief initial repolarization or phase 1. Phase 1 (initial repolarization) is caused by a transient and active potassium efflux (ie, the I_{Kto} current). Calcium begins to move into the intracellular space during phase 0, causing a slower depolarization. Calcium influx continues throughout phase 2 of the AP (plateau phase) and is balanced to some degree by potassium efflux. Calcium entrance (only through L channels in myocardial tissue) distinguishes cardiac conducting cells from nerve tissue and provides the critical ionic link to excitation–contraction coupling and the mechanical properties of the heart as a pump. The membrane remains permeable to potassium efflux during phase 3, resulting in cellular repolarization. Phase 4 of the action potential is the gradual depolarization of the cell and is related to a constant sodium leak into the intracellular space balanced by a decreasing (over time) efflux of potassium. As the cell is slowly depolarized during phase 4, an abrupt increase in sodium permeability occurs, allowing the rapid cellular depolarization of phase 0. The juncture of phase 4 and phase 0, where initiation of rapid sodium influx occurs, is referred to as the threshold potential of the cell.

FIGURE 40-2

Cardiac action potentials and responsible ion currents. While there are similarities between cardiac nodal and muscle action potentials there are many differences in how the phases are influenced by particular ion currents.



Current	Current name
I_{Na}	Sodium current
I_k	Delayed rectifier (slow) Delayed rectifier (fast)
$I_{Ca,T}$	T-type calcium current
$I_{Ca,L}$	L-type calcium current
I_{k1}	Inward rectifier slow
I_f	Funny current
$I_{NCX}(I_{ti})$	Na^+–Ca^{2+} exchanger
I_{to}	Transient outward

Action potential (AP) phase	AP number
Diastolic depolarization	4
Resting membrane potential	4*
Depolarization	0
Fast repolarization	1
Plateau	2
Terminal repolarization	3

Not all cells in the cardiac conduction system rely on sodium influx for initial depolarization. Some tissues depolarize (phase 0) in response to a slower inward ionic current caused by calcium influx (L channels). These "calcium-dependent" tissues are found primarily in the SA and AV nodes (both L and T channels) and possess distinct conduction properties in comparison to "sodium-dependent" fibers (Fig. 40-2). Calcium-dependent cells generally have a slower conduction velocity and a less negative RMP. The RMP in nodal tissue is referred to as the slow depolarization phase or the pacemaker potential. This phase is initiated by the activation of funny current made up of sodium and potassium ions. It is referred to as the "funny" current because unlike most voltage-sensitive currents, it is activated by hyperpolarization. This phase is highly influenced by the autonomic system as seen in Fig. 40-1, panel C. Furthermore, in calcium-dependent tissues, recovery of excitability outlasts full repolarization, whereas in sodium-dependent tissues, recovery is prompt after repolarization. These two types of electrical tissues also differ dramatically in how medications modify their conduction properties.

Ion conductance across the lipid bilayer of the cell membrane occurs via the formation of membrane pores or "channels" (Fig. 40-3). Selective ion channels probably form in response to specific electrical potential differences between the inside and the outside of the cell (voltage dependence). Changes in equilibrium occur and permit the formation of activated ion channels. Besides channel formation and membrane composition, intrachannel proteins or phospholipids, referred to as gates, also regulate the transmembrane movement of ions. These gates are thought to be positioned strategically within the channel to modulate ion flow. Each ion channel conceptually has two types of gates: an activation gate and an inactivation gate (see Fig. 40-3). The activation gate opens during depolarization to allow the ion current to enter or exit from the cell, and the inactivation gate later closes to stop ion movement. When the cell is in a rested state, the activation gates are closed and the inactivation gates are open. The activation gates then open to allow ion movement through the channel, and the inactivation gates later close to stop ion conductance. Thus, the cell cycles between three states: resting, activated, and inactivated. Activation of SA and AV nodal tissue is dependent on a slow depolarizing current through calcium channels and gates, whereas the activation of atrial and ventricular tissues is dependent on a rapid depolarizing current through sodium channels and gates.

FIGURE 40-3

States of sodium (Na^+) channels cycling through the cardiac action potential. Transitions between resting, activated, and inactivated states are dependent on membrane potential and time. The activation gate is shown as m and the inactivation gate as h. Potentials typical for each state are shown under each channel schematic as a function of time. The dashed line indicates that part of the action potential during which most Na^+ channels are completely or partially inactivated and unavailable for reactivation. The impulse that is generated by the SA node disseminates to adjacent cells through gap junctions. The gap junctions provide a pathway for ions to travel to neighboring cells for AP propagation. The compilation of all the cardiac APs is presented on an ECG (Fig. 40-1, panel A). During a normal cardiac conduction cycle the ECG will have a P wave (atrial depolarization), QRS (ventricular depolarization and atrial repolarization), and T wave (ventricular repolarization). It is also important to note the PR interval, or the time from atrial depolarization to ventricular depolarization, and the QT interval, the duration of the ventricular AP (Fig. 40-1, panel B). Augmentation of the ECG is a product of alterations in the cardiac APs.

Abnormal Conduction

The mechanisms of tachyarrhythmias have been classically divided into two general categories: those resulting from an abnormality in impulse generation ("automatic" tachycardia and triggered automaticity) and those resulting from an abnormality in impulse conduction ("reentrant" tachycardias).[1]

Automatic tachycardias depend on spontaneous impulse generation in latent pacemakers and may be a result of several different mechanisms. Medications, such as digoxin or catecholamines, and conditions, such as hypoxia, electrolyte abnormalities (eg, hypokalemia), and fiber stretch (cardiac dilation), may lead to an increased slope of phase 4 depolarization in cardiac tissues other than the SA node.[1] These factors are associated with abnormal automaticity in experimental models and arrhythmogenesis in clinical situations. The increased slope of phase 4 causes heightened automaticity of these tissues and competition with the SA node for dominance of cardiac rhythm. If the rate of spontaneous impulse generation of the abnormally automatic tissue exceeds that of the SA node, then an automatic tachycardia may result. Automatic tachycardias have the following characteristics: (a) the onset of the tachycardia is unrelated to an initiating event such as a premature beat; (b) the initiating beat is usually identical to subsequent beats of the tachycardia; (c) the tachycardia cannot be initiated by programmed cardiac stimulation; and (d) the onset of the tachycardia is usually preceded by a gradual acceleration in rate and termination is usually preceded by a gradual deceleration in rate. Clinical tachycardias resulting from the classic forms of enhanced automaticity are not as common as once thought. Examples are sinus tachycardia and junctional tachycardia.

Triggered automaticity is also a possible mechanism for abnormal impulse generation. Briefly, triggered automaticity refers to transient membrane depolarizations that occur during repolarization (early afterdepolarizations [EADs]) or after repolarization (delayed afterdepolarizations [DADs]) but prior to phase 4 of the AP (Fig. 40-4).[1] Afterdepolarizations may be related to abnormal calcium and sodium influx during or just after full cellular repolarization. Experimentally, EADs may be precipitated by hypokalemia, class Ia AADs, or slow stimulation rates—any factor that blocks the ion channels (eg, potassium) responsible for cellular repolarization. EADs provoked by medications that block potassium conductance and delay repolarization are the underlying cause of TdP. DADs may be precipitated by digoxin or catecholamines and suppressed by non-dihydropyridine (non-DHP) calcium channel blockers (CCBs). DADs have been suggested as the mechanism for multifocal atrial tachycardia, digoxin-induced tachycardias, and exercise-provoked VT. Triggered automatic rhythms possess some of the characteristics of automatic tachycardias and some of the characteristics of reentrant tachycardias (description follows).

FIGURE 40-4

Afterdepolarizations. (EAD early afterdepolarization; DAD delayed afterdepolarization.)

Reentry is a concept that involves indefinite propagation of the impulse and continued activation of previously refractory tissue. There are three conduction requirements for the formation of a viable reentrant focus: (1) two pathways for impulse conduction, (2) an area of unidirectional block (prolonged refractoriness) in one of these pathways, and (3) slow conduction in the other pathway (Fig. 40-5, panel A).[1] Usually, a critically timed premature beat initiates reentry. This premature impulse enters both conduction pathways but encounters refractory tissue in one of the pathways at the area of unidirectional block. The impulse dies out because the tissue is still refractory from the previous (sinus) impulse. Although it fails to propagate in one pathway, the impulse may still proceed in a forward direction (antegrade) through the other pathway because of this pathway's relatively shorter refractory period. The impulse may then proceed through a loop of tissue and "reenter" the area of unidirectional block in a backward direction (retrograde). Because the antegrade pathway has slow conduction characteristics, the area of unidirectional block has time to recover its excitability. The impulse can proceed in a retrograde fashion through this previously refractory tissue and continue around the loop of tissue in a circular fashion. Thus, the key to the formation of a reentrant focus is crucial conduction discrepancies in the electrophysiologic characteristics of the two pathways. The reentrant focus may excite surrounding tissue at a rate greater than that of the SA node, leading to the formation of a clinical tachycardia. The above model is anatomically determined in that there is only one pathway for impulse conduction with a fixed circuit length.

FIGURE 40-5

(*A*) Possible mechanism of proarrhythmia in the anatomic model of reentry. (1a) Nonviable reentrant loop due to bidirectional block (*shaded area*). (1b) Instance where a medication slows conduction velocity without significantly prolonging the refractory period. The impulse is now able to reenter the area of unidirectional block (*shaded area*) because slowed conduction through the antegrade pathway allows recovery of the block. A new reentrant tachycardia may result. (2a) Nonviable reentrant loop due to a lack of a unidirectional block. (2b) Instance where a medication prolongs the refractory period without significantly slowing conduction velocity. The impulse moving antegrade meets refractory tissue (*shaded area*), allowing for unidirectional block. A new reentrant tachycardia may result. (*B*) Mechanism of functional reentry and proarrhythmia. (a) Functionally determined reentrant circuit. This model should be contrasted with anatomic reentry; here, the circuit is not fixed (it does not necessarily move around an anatomic obstacle), and there is no excitable gap. All tissue inside is held continuously refractory. (b) An instance where a medication prolongs the refractory period without significantly slowing conduction velocity. The tachycardia may terminate or slow in rate as shown as a consequence of a greater circuit length. The *dashed lines* represent the original reentrant circuit prior to medication treatment. (c) An instance where a medication slows conduction velocity without significantly prolonging the refractory period (ie, class Ic *antiarrhythmic medications*) and accelerates the tachycardia. The tachycardia rate may increase (proarrhythmia) as shown as a consequence of a shorter circuit length. The dashed lines represent the original reentrant circuit prior to medication treatment. (*Reprinted, with permission, from McCollam PL, Parker RB, Beckman KJ, et al. Proarrhythmia: A paradoxic response to antiarrhythmic agents. Pharmacotherapy 1989;9:146.*)

Another model of reentry, referred to as a functional reentrant loop, may also occur (Fig. 40-5, panel B).[1] In a functional reentrant focus, the length of the circuit may vary depending on the conduction velocity and recovery characteristics of the impulse. The area in the middle of the loop is continually kept refractory by the inwardly moving impulse. The length of the circuit is not fixed but is the smallest circle possible, such that the leading edge of the wave front is continuously exciting tissue just as it recovers. It differs from the anatomic model in that the leading edge of the impulse is not preceded by an excitable gap of tissue, and it does not have an obstacle in the middle or a fixed anatomic circuit.

Clinically, many reentrant foci probably have both anatomic and functional characteristics. All of these theoretical models require a critical balance of refractoriness and conduction velocity within the circuit and, as such, have helped to explain the effects of medications on terminating, modifying, and causing cardiac rhythm disturbances (eg, proarrhythmia).

What causes reentry to become clinically manifest? Reentrant foci may occur at any level of the conduction system: within the branches of the specialized atrial conduction system, within the Purkinje network, and even within portions of the SA and AV nodes. The anatomy of the Purkinje system appears to provide a suitable substrate for the formation of microreentrant loops and is often used as a model to facilitate the understanding of reentry concepts. Of course, because reentry does not usually occur in normal, healthy conduction tissue, various forms of heart disease or conduction abnormalities are typically present before reentry becomes manifest. An often-used example is reentry occurring as a consequence of ischemic or hypoxic damage. With inadequate cellular oxygenation, high-energy phosphate concentrations diminish, the activity of the transmembrane ion pumps declines, and RMP rises. This rise in RMP causes inactivation in the voltage-dependent sodium channel, and the tissue begins to assume slow conduction characteristics. If changes in the tissue's conduction parameters occur in a discordant manner due to varying degrees of ischemia or hypoxia, then a reentry circuit may become manifest. Furthermore, an ischemic, dying cell releases intracellular potassium, which also causes a rise in RMP. In other cases, reentry may occur because of anatomic or functional variants in the normal conduction system. For instance, patients may possess two (instead of one) conduction pathways near or within the AV node or have an anomalous extranodal AV pathway that possesses different electrophysiologic characteristics from the normal AV nodal pathway. Reentry in these cases may occur within the AV node or encompass both atrial and ventricular tissues. Reentrant tachycardias have the following characteristics: (a) the onset of the tachycardia is usually related to an initiating event (ie, premature beat); (b) the initiating beat is usually different in morphology from subsequent beats of the tachycardia; (c) the initiation of the tachycardia can usually be incited with programmed cardiac stimulation; and (d) the initiation and termination of the tachycardia is usually abrupt without an acceleration or deceleration phase. There are many examples of reentrant tachycardias, including AF, atrial flutter (AFl), AV nodal reentrant tachycardia (AVNRT), AV reentrant tachycardia (AVRT), and recurrent VT (Table 40-1).

TABLE 40-1

Characteristics and Presumed Mechanisms of Arrhythmias

Tachycardia	Mechanism	Origin
Sinus tachycardia	Automatic (normal)	Sinus node
Atrial fibrillation	Reentry, automatic, triggered activity	Atria, thoracic veins, pulmonary veins, and superior vena cava
Atrial flutter	Reentry	Right (most common) and left atria
Atrial tachycardia	Reentry, automatic, triggered activity	Atria
AV nodal reentry tachycardia	Reentry	AV junction
AV reentry tachycardia	Reentry	Circuit includes accessory AV connection, atria, AV node, His-Purkinje system, ventricles
Ventricular tachycardia	Reentry, automatic, triggered	Ventricles
Torsades de Pointes	Reentry, triggered activity	Ventricles

AV, atrioventricular.

PHARMACOLOGIC THERAPY

In a theoretical sense, medications have antiarrhythmic activity by directly altering electrical conduction in several ways. First, a medication may depress the automatic properties of abnormal pacemaker cells. If the rate of spontaneous impulse generation of the abnormally automatic foci becomes less than that of the SA node, normal cardiac rhythm can be restored. Second, medications may alter the conduction characteristics of a reentrant loop (Fig. 40-5).[1,2] A medication may facilitate conduction (shorten refractoriness) in the area of unidirectional block, allowing antegrade conduction to proceed. On the other hand, a medication may further depress conduction (prolong refractoriness) either in the area of unidirectional block or in the pathway with slowed conduction and a relatively shorter refractory period. If refractoriness is prolonged in the area of unidirectional block, retrograde propagation of the impulse is not permitted, causing a "bidirectional" block. In the anatomic model, if refractoriness is prolonged in the pathway with slow conduction, antegrade conduction of the impulse is not permitted. In either case, medications that reduce the discordance and cause uniformity in conduction properties of the two pathways may suppress the reentrant substrate. In the functionally determined model, if refractoriness is prolonged without significantly slowing conduction velocity, the tachycardia may terminate or slow in rate because of a greater circuit length (see Fig. 40-5, panel B). There are other theoretical ways to stop reentry: (a) a medication may eliminate the critically timed premature impulse that triggers reentry; (b) a medication may slow conduction velocity to such an extent that conduction is extinguished; or (c) a medication may reverse the underlying form of heart disease that was responsible for the conduction abnormalities that led to the arrhythmia (ie, “reverse remodeling”).

AADs have specific electrophysiologic actions that alter cardiac conduction in patients with or without heart disease. These actions form the basis of grouping AADs into specific categories based on their electrophysiologic actions in vitro. Vaughan Williams proposed the most frequently used classification system (Table 40-2).[2] This classification has been criticized for the following reasons: (a) it is incomplete and does not allow for the classification of medications such as digoxin or adenosine; (b) it is not pure, and many agents have properties of more than one class of medications; (c) it does not incorporate medication characteristics such as mechanisms of tachycardia termination/prevention, clinical indications, or side effects; and (d) medications become “labeled” within a class, although they may be distinct in many regards. Despite these criticisms, the Vaughan Williams classification remains the most frequently used for categorizing the electrophysiologic actions of AADs.

TABLE 40-2

Classification of Antiarrhythmic Medications

Class	Medication	Conduction Velocity[a]	Refractory Period	Automaticity	Ion Block
Ia	Quinidine	↓	↑	↓	Sodium (intermediate) Potassium
	Procainamide				
	Disopyramide				
Ib	Lidocaine	0/↓	↓	↓	Sodium (fast on–off)
	Mexiletine				
Ic	Flecainide	↓↓	↑ (atrial)	↓	Sodium (slow on–off)
	Propafenone[b]				
II[c]	β-blockers	↓	↑	↓	Calcium (indirect)
III	Amiodarone[d]	0	↑↑	0	Potassium
	Dofetilide				
	Dronedarone[d]				
	Sotalol[b]				
	Ibutilide				
IV[c]	Verapamil	↓	↑	↓	Calcium
	Diltiazem				

[a] Variables for normal tissue models in ventricular tissue.

[b] Also has β-blocking actions.

[c] Variables for sinoatrial (SA) and atrioventricular (AV) nodal tissue only.

[d] Also has sodium, calcium, and β-blocking actions; see Table 40-3.

TABLE 40-3

Time Course and Electrophysiologic Effects of Amiodarone

				IV		Oral	
Class	**Mechanism**	**EP**	**ECG**	**Minutes–Hours**	**Hours–Days**	**Days–Weeks**	**Weeks–Months**
Class I	Na$^+$ block	↑HV	↑QRS	0	+	+	++
Class II	β-block	↑AH	↑PR	++	++	++	++
			↓HR				
Class III	K$^+$ block	↑VERP	↑QT	0	+	++	++++
		↑AERP					
Class IV	Ca^{2+} block[a]	↑AH	↑PR	+	+	+	+
			↓HR				

AERP, atrial effective refractory period; AH, atria–His interval; ECG, electrocardiographic effects; EP, electrophysiologic actions; HR, heart rate; HV, His–ventricle interval; IV, intravenous; VERP, ventricular effective refractory period.

[a] Rate-dependent (for amiodarone).

Class I AADs are grouped together because of their common action in blocking sodium conductance. The receptor site for these AADs is probably inside the sodium channel so that, in effect, the medication plugs the pore. The AAD may gain access to the receptor either via the intracellular space through the membrane lipid bilayer or directly through the channel (Fig. 40-3). Several principles are inherent in antiarrhythmic sodium channel receptor theories[3,4]:

1. Class I AADs have predominant affinity for a particular state of the channel (eg, during activation or inactivation). For example, lidocaine blocks sodium current primarily when the cell is in the inactivated state, whereas quinidine, flecainide, and propafenone are predominantly open (or activated) channel blockers.
2. Class I AADs have specific binding and unbinding characteristics to the receptor, which has led to the subclassification (Ia, Ib, Ic) of these AADs. For example, lidocaine binds to and dissociates from the channel receptor quickly ("fast on–off") but flecainide has very "slow on–off" properties. This explains why flecainide has such potent effects on slowing ventricular conduction, whereas lidocaine has little effect on normal tissue (at normal heart rates). In general, the class Ic AADs are "slow on–off," the class Ib AADs are "fast on–off," and the class Ia AADs are intermediate in their binding kinetics.
3. Class I AADs possess use dependence (ie, sodium channel blockade and slowed conduction are greatest at fast heart rates and least during bradycardia). For "slow on–off" medications, sodium channel blockade is evident at normal rates (60 to 100 beats/min), but for "fast on–off" agents, slowed conduction is only apparent at fast heart rates.
4. Class I AADs are weak bases with a pKa > 7 and block the sodium channel in their ionized form. Consequently, pH will alter these actions: acidosis accentuates, and alkalosis diminishes sodium channel blockade.
5. Class I AADs appear to share a single receptor site in the sodium channel. It should be noted, however, that a number of class I AADs have other electrophysiologic properties. For instance, quinidine has potent potassium channel blocking activity (manifests predominantly at low

concentrations) as does N-acetylprocainamide (manifests predominantly at high concentrations), the primary metabolite of procainamide. Additionally, propafenone has β-blocking actions.

The class Ia AADs, quinidine, procainamide, and disopyramide, slow conduction velocity, prolong refractoriness, and decrease the automatic properties of sodium-dependent (normal and diseased) conduction tissue. Although class Ia AADs are primarily considered sodium channel blockers, their electrophysiologic actions can also be attributed to blockade of potassium channels. In reentrant tachycardias, these medications generally depress conduction and prolong refractoriness, theoretically transforming the area of unidirectional block into a bidirectional block. Clinically, class Ia medications are broad-spectrum AADs that are indicated for both supraventricular and ventricular arrhythmias. However, their use tends to be infrequent in clinical practice because of their limited efficacy and significant toxicities.

The class Ib AADs, lidocaine and mexiletine were historically categorized separately from quinidine-like medications. Early work demonstrated that lidocaine had distinctly different electrophysiologic actions. In normal tissue models, lidocaine generally facilitates actions on cardiac conduction by shortening refractoriness and having little effect on conduction velocity. Thus, it was postulated that these agents could improve antegrade conduction, eliminating the area of unidirectional block. Arrhythmias do not usually arise from normal tissue. However, lidocaine possesses class Ia quinidine-like properties in diseased tissues. Therefore, it is probable that lidocaine acts in a similar fashion to the class Ia AADs (ie, prolongs refractoriness) in diseased ischemic tissues leading to bidirectional block in a reentrant circuit. Lidocaine and similar agents have accentuated effects in ischemic tissue caused by the local acidosis and potassium shifts that occur during cellular hypoxia. Changes in pH alter the time that local anesthetics, like lidocaine, occupy the sodium channel receptor, affecting the agent's electrophysiologic actions. In addition, the intracellular acidosis that ensues due to ischemia could cause lidocaine to become "trapped" within the cell, allowing increased access to the receptor. The class Ib AADs are considerably more effective in ventricular arrhythmias than supraventricular arrhythmias. As a group, these medications are relatively weak sodium channel blockers (at normal stimulation rates).

The class Ic AADs, propafenone and flecainide, are extremely potent sodium channel blockers, profoundly slowing conduction velocity while leaving refractoriness relatively unaltered. The class Ic AADs theoretically eliminate reentry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. Although the class Ic AADs are effective for both ventricular and supraventricular arrhythmias, their use for ventricular arrhythmias has been limited by the risk of proarrhythmia.

The β-blockers are classified as class II AADs. For the most part, the clinically relevant acute antiarrhythmic mechanisms of the β-blockers result from their antiadrenergic actions.[4] Because the SA and AV nodes are heavily influenced by adrenergic innervation, β-blockers would be most useful in tachycardias in which these nodal tissues are abnormally automatic or are a portion of a reentrant loop. These medications are also helpful in slowing ventricular response in atrial arrhythmias (eg, AF) by their effects on the AV node. Furthermore, some tachycardias are exercise-related or precipitated by states of high sympathetic tone (perhaps through triggered activity), and β-blockers may be useful in these instances. Beta-adrenergic stimulation results in increased conduction velocity, shortened refractoriness, and increased automaticity of the nodal tissues; β-blockers will antagonize these effects. In the nodal tissues, β-blockers interfere with calcium entry into the cell by altering catecholamine-dependent channel integrity and gating kinetics. In sodium-dependent atrial and ventricular tissues, β-blockers shorten repolarization somewhat but otherwise have little direct effect. The antiarrhythmic properties of β-blockers observed with long-term, chronic therapy in patients with heart disease are less well understood. Although it is clear β-blockers decrease the likelihood of SCD (presumably arrhythmic death) after MI, the mechanism for this benefit remains unclear; this benefit may relate to the complex interplay of changes in sympathetic tone, damaged myocardium, and ventricular conduction. In patients with HF, medications such as β-blockers, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers may prevent arrhythmias such as AF by attenuating the structural and/or electrical remodeling process in the myocardium.[5]

The class III AADs include those agents that specifically prolong refractoriness in atrial and ventricular tissues. This class includes amiodarone, dronedarone, sotalol, ibutilide, and dofetilide. These medications share the common effect of delaying repolarization by blocking potassium channels. Amiodarone and sotalol are effective in most supraventricular and ventricular arrhythmias. Amiodarone displays electrophysiologic characteristics of all four Vaughan Williams classes; it is a sodium channel blocker with relatively "fast on–off" kinetics, has nonselective β-blocking actions, blocks potassium channels, and has a small degree of calcium channel blocking activity (Table 40-3). At normal heart rates and with chronic use, its predominant effect is to prolong repolarization. With IV administration, its onset is relatively quick (unlike the oral form) and beta blockade predominates initially. Theoretically, amiodarone, like class I AADs, may interrupt the reentrant substrate by transforming an area of unidirectional block into an area of bidirectional block. However, amiodarone may leave the reentrant loop intact. The impressive effectiveness of amiodarone coupled with its low proarrhythmic potential has challenged the notion that selective ion channel blockade by AADs is preferable. Sotalol is a potent inhibitor of outward potassium movement during repolarization and possesses nonselective β-blocking actions. Unlike amiodarone and sotalol, dronedarone, ibutilide, and dofetilide are only approved for the treatment of supraventricular arrhythmias. Both ibutilide (only available IV) and dofetilide (only available orally) can be used for the acute conversion of AF or AFl to SR. Dofetilide can also be used to maintain SR in patients with AF or AFl of longer than 1 week's duration who have been converted to SR. Dronedarone is approved to reduce the risk of hospitalization in patients with a history of paroxysmal or persistent AF who are currently in SR. Although structurally related to amiodarone, dronedarone's structure has been modified through the addition of a methylsulfonyl group and the removal of iodine. Dronedarone is also similar to amiodarone in exhibiting electrophysiologic characteristics of all four Vaughan Williams classes (sodium channel blocker with relatively "fast on–off" kinetics, nonselective β-blocker, potassium channel blocker, and calcium channel antagonist). However, amiodarone is more effective than dronedarone.

There are several different potassium channels that function during normal conduction; all approved class III AADs inhibit the delayed rectifier current (I_K) responsible for phase 2 and phase 3 repolarization. Subcurrents make up I_K: an ultrarapid component (I_{Kur}), a rapid component (I_{Kr}), and the slow component (I_{Ks}). Sotalol, ibutilide, and dofetilide selectively block I_{Kr}, whereas amiodarone and dronedarone block both I_{Kr} and I_{Ks}. Potassium channel blockers (particularly those with selective I_{Kr} blocking properties) display "reverse use dependence" (ie, their effects on repolarization are greatest at low heart rates). Sotalol and medications like it also appear to be much more effective in preventing VF (in dog models) than the traditional sodium channel blockers. The safety concern of all class III AADs is an extension of their underlying ionic mechanism; that is, by blocking potassium channels and delaying repolarization, these medications may also cause proarrhythmia in the form of TdP by provoking EADs.

The non-DHP CCBs, verapamil and diltiazem, are categorized as class IV AADs. They block L-type calcium channels in SA and AV nodal tissues, slowing conduction, prolonging refractoriness, and decreasing automaticity (eg, due to EADs or DADs). Thus, these agents are effective in automatic or reentrant tachycardias which arise from or use the SA or AV nodes. In supraventricular arrhythmias (eg, AF or AFl), these medications can slow ventricular response by slowing AV nodal conduction. Furthermore, because calcium entry seems to be integral to exercise-related tachycardias and/or tachycardias caused by some forms of triggered automaticity, these agents may be effective in the treatment of these types of arrhythmias. The DHP CCBs (eg, nifedipine) do not have significant antiarrhythmic activity as they do not affect AV nodal conduction.

② All AADs currently available have an impressive side effect profile (Table 40-4). A considerable percentage of patients cannot tolerate long-term therapy with these medications and will have to discontinue therapy because of adverse drug reactions. Flecainide, propafenone, quinidine, procainamide, disopyramide, sotalol, non-DHP CCBs, and dronedarone may worsen HF symptoms in patients with underlying LV systolic dysfunction. Consequently, these medications should be avoided in patients with HFrEF. The class Ib AAD, mexiletine, causes neurologic and/or gastrointestinal toxicity in a high percentage of patients. One of the most frightening adverse effects related to AADs is the aggravation of underlying ventricular arrhythmias or the precipitation of new, life-threatening ventricular arrhythmias.[4]

TABLE 40-4

Adverse Drug Reactions of Class I and III Antiarrhythmic Medications

Disopyramide	Anticholinergic symptoms (dry mouth, urinary retention, constipation, blurred vision), nausea, anorexia, HF, conduction disturbances, ventricular arrhythmias (eg, TdP)
Procainamide	Hypotension, worsening HF, conduction disturbances, ventricular arrhythmias (eg, TdP)
Quinidine	Cinchonism, diarrhea, abdominal cramps, nausea, vomiting, hypotension, worsening HF, conduction disturbances, ventricular arrhythmias (eg, TdP), fever
Lidocaine	Dizziness, sedation, slurred speech, blurred vision, paresthesia, muscle twitching, confusion, nausea, vomiting, seizures, psychosis, sinus arrest, conduction disturbances
Mexiletine	Dizziness, sedation, anxiety, confusion, paresthesia, tremor, ataxia, blurred vision, nausea, vomiting, anorexia, conduction disturbances, ventricular arrhythmias
Flecainide	Blurred vision, dizziness, dyspnea, headache, tremor, nausea, worsening HF, conduction disturbances, ventricular arrhythmias
Propafenone	Dizziness, fatigue, blurred vision, bronchospasm, headache, taste disturbances, nausea, vomiting, bradycardia or AV block, worsening HF, ventricular arrhythmias
Amiodarone	Tremor, ataxia, paresthesia, insomnia, corneal microdeposits, optic neuropathy/neuritis, nausea, vomiting, anorexia, constipation, TdP (<1%), bradycardia or AV block (IV and oral use), pulmonary fibrosis, liver function test abnormalities, hypothyroidism, hyperthyroidism, photosensitivity, blue-gray skin discoloration, hypotension (IV use), phlebitis (IV use)
Dofetilide	Headache, dizziness, TdP
Dronedarone	Nausea, vomiting, diarrhea, serum creatinine elevations, bradycardia, worsening HF, hepatotoxicity, pulmonary fibrosis, acute renal failure, TdP (<1%)
Ibutilide	Headache, TdP, bradycardia or AV block, hypotension
Sotalol	Dizziness, weakness, fatigue, nausea, vomiting, diarrhea, bradycardia or AV block, TdP, bronchospasm, worsening HF

AV, atrioventricular; HF, heart failure; IV, intravenous; TdP, torsades de pointes.

③ Amiodarone has assumed a prominent place in the treatment of both acute and chronic supraventricular and ventricular arrhythmias and is the most commonly prescribed AAD.[6] Once considered a medication of last resort, it is often the first AAD considered for the treatment of many arrhythmias. Yet amiodarone is a peculiar and complex medication, displaying unusual pharmacologic effects, pharmacokinetics, dosing regimens, and multiorgan adverse drug reactions. Amiodarone has an extremely long elimination half-life (approximately 60 days) and a large volume of distribution. Consequently, the onset of action with the oral form is delayed (days to weeks) despite the use of a loading regimen, and the duration of effect may persist for months after discontinuation. Amiodarone is a substrate of the cytochrome P450 (CYP) 3A4 isoenzyme, a moderate inhibitor of many CYP isoenzymes (eg, CYP2C9, CYP2D6, CYP3A4), and a P-glycoprotein (P-gp) inhibitor, which can result in numerous medication interactions.[7] By inhibiting P-gp, amiodarone can increase digoxin concentrations by approximately twofold; therefore, the digoxin dose should be empirically reduced by 50% when initiating amiodarone. By inhibiting CYP2C9 and CYP3A4, amiodarone can increase warfarin concentrations and the international normalized ratio (INR). Consequently, when amiodarone and warfarin are initiated concurrently, an empiric warfarin dose reduction is necessary. When amiodarone is initiated in a patient already receiving warfarin, close INR monitoring is needed and the dose of warfarin may need to be reduced by approximately 30%.[8]

Acute administration of amiodarone is usually well tolerated by patients; however, severe organ toxicities may result with chronic use. Severe bradycardia, hyperthyroidism, hypothyroidism, peripheral neuropathy, gastrointestinal discomfort, and photosensitivity are common. Fulminant hepatitis (uncommon) and pulmonary fibrosis (2% of patients) have caused death.[6] While amiodarone can cause benign corneal microdeposits in virtually every patient, it has also been associated with the development of optic neuropathy/neuritis which can lead to blindness. Even though amiodarone may markedly prolong the QT interval, proarrhythmia (ie, TdP) is rare. All of these adverse drug reactions mandate close, continued monitoring (liver enzymes, thyroid function tests, eye examinations, chest radiographs, pulmonary function tests), leading to a proliferation of "amiodarone clinics" designed for patients treated chronically with amiodarone (Table 40-5).[6]

TABLE 40-5

Amiodarone Monitoring

Adverse Drug Reaction	Monitoring Recommendations	Management of Adverse Drug Reactions
Pulmonary fibrosis	Chest radiograph (baseline, and then every 12 months)	Discontinue amiodarone immediately; may consider corticosteroid therapy
	Pulmonary function tests (baseline, and then if symptoms develop)	
	High-resolution CT (if symptoms develop)	
Hypothyroidism	TFTs (baseline, and then every 6 months)	Thyroid hormone supplementation (eg, levothyroxine)
Hyperthyroidism	TFTs (baseline, and then every 6 months)	Antithyroid medications (eg, methimazole, propylthiouracil) or corticosteroids; may need to discontinue amiodarone
Optic neuritis/neuropathy	Ophthalmologic examination (baseline [only if visual impairment present], and then if symptoms develop)	Discontinue amiodarone immediately
Corneal microdeposits	Slit-lamp examination (routine monitoring not necessary)	No treatment necessary
Hepatotoxicity	LFTs (baseline, and then every 6 months)	Lower the dose or discontinue amiodarone if LFTs >2× the upper limit of normal
Bradycardia/heart block	ECG (baseline, and then every 6 months or as clinically indicated)	Lower the dose, if possible, or discontinue amiodarone if severe (or continue amiodarone and implant permanent pacemaker)
Tremor, ataxia, peripheral neuropathy	History/physical examination (each office visit)	Lower the dose, if possible, or discontinue amiodarone if severe
Photosensitivity	History/physical examination (each office visit)	Lower the dose; advise patients to wear sunblock while outdoors

ECG, electrocardiogram; LFTs, liver function tests; TFTs, thyroid function tests.

Dronedarone has a considerably shorter half-life (approximately 24 hours) when compared with amiodarone which allows for steady state to be achieved in 5 to 7 days without the need for loading doses. Like amiodarone, dronedarone is a substrate of the CYP3A4 isoenzyme and a moderate inhibitor of the CYP2D6 and CYP3A4 isoenzymes. Its use with potent CYP3A4 inhibitors or inducers should be avoided. Dronedarone may increase plasma concentrations of (*S*)-warfarin; therefore, the INR should be closely monitored with concurrent use of these medications. Dronedarone also inhibits P-gp and can increase digoxin concentrations by about 2.5-fold. Consequently, when concomitantly using dronedarone and digoxin, the digoxin dose should be empirically reduced by 50%. Additionally, dronedarone can increase dabigatran concentrations in patients with renal impairment. To minimize the risk of bleeding when concomitantly using dronedarone and dabigatran in patients with moderate renal impairment (creatinine clearance [CrCl] 30-50 mL/min [0.5-0.83 mL/s]), the dose of dabigatran should be reduced to 75 mg twice daily. The concomitant use of dronedarone and dabigatran should be avoided in patients with severe renal impairment (CrCl less than 30 mL/min [0.5 mL/s]).

Modifications to the chemical structure of dronedarone (addition of a methylsulfonyl group, deletion of the iodine moiety) result in it being less lipophilic than amiodarone. Consequently, dronedarone is supposed to be less likely to accumulate in tissues and cause various organ toxicities. However, like amiodarone, several post-marketing reports have linked dronedarone to significant organ toxicities, including severe hepatic injury, interstitial lung disease (ie, pulmonary fibrosis), and acute kidney injury.[9-11]

Table 40-6 summarizes potential sites/mechanisms for drug interactions with the AADs and Table 40-7 lists recommended dosages of the oral dosage forms of the AADs. Table 40-8 lists the dosing recommendations for the IV forms of various AADs.

TABLE 40-6

Potential Mechanisms for Drug-Drug Interactions with Antiarrhythmic Medications

Medication	Substrate	Inhibitor
Disopyramide	CYP3A4 (M)	—
Procainamide	NAT CYP2D6 (M)	—
Quinidine	CYP3A4 (M) CYP2C9	CYP2D6 (S) CYP3A4 (S) CYP2C9 P-gp
Lidocaine	CYP3A4 (M) CYP2D6 (M) CYP1A2 CYP2C9	CYP1A2 (S) CYP2D6
Mexiletine	CYP2D6 (M) CYP1A2 (M)	CYP1A2 (S)
Flecainide	CYP2D6 (M) CYP1A2	CYP2D6
Propafenone[a]	CYP2D6 (M) CYP1A2 CYP2D6	CYP1A2 CYP2D6

Amiodarone	CYP3A4 (M) CYP1A2 CYP2C19 CYP2D6	CYP2C9 CYP2D6 CYP3A4 CYP1A2 CYP2C19 P-gp

[a] Variables for parent compound (not 5-OH-propafenone).

CYP, cytochrome P450 isoenzyme; M, major; NAT, N -acetyltransferase; P-gp, P-glycoprotein; S, strong.

TABLE 40-7

Typical Maintenance Doses of Class I and Class III Oral Antiarrhythmic Medications

Medication	Dose	Dose Adjustments
Disopyramide	Immediate-release: 100-150 mg every 6 hours Controlled-release: 200-300 mg every 12 hours	**Chronic kidney disease** CrCl 30-40 mL/min (0.5-0.67 mL/s): 100 mg every 8 hours CrCl 15-30 mL/min (0.25-0.5 mL/s): 100 mg every 12 hours CrCl < 15 mL/min (0.25 mL/s): 100 mg daily *Note:* Avoid controlled release formulation if CrCl <40 mL/min (0.67 mL/s) **Hepatic impairment** Immediate-release: 100 mg every 6 hours Controlled-release: 200 mg every 12 hours

Quinidine	200-600 mg sulfate every 6 hours 324-648 gluconate every 8-12 hours	**Chronic kidney disease** No dosage adjustment. Use with caution. The following guidelines have been used by some clinicians[12]: CrCl ≥10 mL/min (0.17 mL/s): No dosage adjustment CrCl <10 mL/min (0.17 mL/s): Administer 75% of normal dose. Hemodialysis: Dose following hemodialysis. **Hepatic impairment** No dosage adjustment. Use with caution due to reduced clearance.
Mexiletine	200-300 mg every 8 hours	**Hepatic impairment** No dose adjustment provided. Use caution as half-life doubles with hepatic impairment.
Flecainide	50-200 mg every 12 hours	**Chronic kidney disease** CrCl >35 mL/min (0.58 mL/s): Initial: 100 mg every 12 hours. Dose increases should be made very cautiously at intervals >4 days. CrCl ≤35 mL/min (0.58 mL/s): Initial: 100 mg once daily or 50 mg every 12 hours. Dose increases should be made very cautiously at intervals >4 days. **Hepatic impairment** No dose adjustment provided. Use caution.
Propafenone	150-300 mg every 8 hours 225-425 mg every 12 hours (SR form)	**Chronic kidney disease** No dose adjustment provided. Use caution. **Hepatic impairment** No dose adjustment provided. Use caution.
Amiodarone	400 mg one to three times daily until 10 g total, then 100-400 mg daily	None
Dofetilide	500 µg every 12 hours	**Chronic kidney disease** CrCl >60 mL/min (1.0 mL/s): No dosage adjustment. CrCl 40 to 60 mL/min (0.67-1.0 mL/s): 250 µg twice daily. CrCl 20 to 39 mL/min (0.33-0.65 mL/s): 125 µg twice daily. CrCl <20 mL/min (0.33 mL/s): Use is contraindicated. **Hepatic impairment** Child-Pugh class A or B: No dosage adjustment. Child-Pugh class C: Use caution.
Dronedarone	400 mg twice daily (with meals)	**Hepatic impairment** Severe impairment: Contraindicated.
Sotalol	80-320 mg every 12 hours	**Chronic kidney disease** *Atrial fibrillation/flutter* CrCl >60mL/min: No dosage adjustment CrCl 30 to 60 mL/min: Administer every 24 hours CrCl <30 mL/min: Avoid use

		Ventricular arrhythmia CrCl >60 mL/min: No dosage adjustment CrCl 30 to 60 mL/min: Administer every 24 hours CrCl 10 to 29 mL/minute: Administer every 36 to 48 hours CrCl <10 mL/min: Individualized

SR, sustained release.

TABLE 40-8

Typical Doses of IV Antiarrhythmic Medications

Medication	Clinical Situation	Dose
Amiodarone	Pulseless VT/VF	300 mg IV/IO push (can give additional 150 mg IV/IO push if persistent VT/VF or if VT/VF recurs), followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min × 18 hours
	Stable VT (with a pulse)	150 mg IV over 10 minutes, followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min × 18 hours
	AF (termination)	150 mg IV over 10 minutes, followed by infusion of 1 mg/min for 6 hours, and then 0.5 mg/min × 18 hours
	AF (rate control)	300 mg IV over 1 hour, then 10-50 mg/hour over 24 hours
Diltiazem	PSVT; AF (rate control)	0.25 mg/kg IV over 2 minutes (may repeat with 0.35 mg/kg IV over 2 minutes), followed by infusion of 5-15 mg/hr
Ibutilide	AF (termination)	1 mg IV over 10 minutes (may repeat once, if needed, 10 minutes after initial dose)
Lidocaine	Pulseless VT/VF	1-1.5 mg/kg IV/IO push (can give additional 0.5-0.75 mg/kg IV/IO push every 5-10 minutes if persistent VT/VF [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1-4 mg/min (1-2 mg/min if liver disease or HF)
	Stable VT (with a pulse)	1-1.5 mg/kg IV push (can give additional 0.5-0.75 mg/kg IV push every 5-10 minutes if persistent VT [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1-4 mg/min (1-2 mg/min if liver disease or HF)
Procainamide	AF (termination); stable VT (with a pulse)	15-18 mg/kg IV over 60 minutes, followed by infusion of 1-4 mg/min
Verapamil	PSVT; AF (rate control)	2.5-5 mg IV over 2 minutes (may repeat up to maximum cumulative dose of 20 mg); can follow with infusion of 2.5-10 mg/hr

AF, atrial fibrillation; HF, heart failure; IO, intraosseous; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

Supraventricular Arrhythmias

The common supraventricular tachycardias that often require medication treatment are: (a) AF or AFl; (b) PSVT; and (c) automatic atrial tachycardias. Other common supraventricular arrhythmias that usually do not require medication therapy include premature atrial complexes and sinus tachycardia. For example, premature atrial complexes rarely cause symptoms and never cause hemodynamic compromise; therefore, medication therapy is usually not indicated. Likewise, the cause of sinus tachycardia is often an underlying metabolic or hemodynamic disorder (eg, infection, dehydration, hypotension); therapy should focus on treating the underlying cause, not the tachycardia. Of course, there are exceptions to these suggestions. For example, sinus tachycardia may be deleterious in patients after cardiac surgery or MI. Therefore, AADs, such as β-blockers, may be indicated in these situations. Stated in another way, although many arrhythmias generally do not require therapy, clinical judgment and patient-specific variables play an important role in this decision. AF, AFl, and PSVT tend to be the most common supraventricular arrhythmias seen in clinical practice; therefore, this discussion will focus only on these arrhythmias.

Atrial Fibrillation and Atrial Flutter

AF continues to be the most common sustained arrhythmia encountered in clinical practice, affecting approximately 5 million Americans.[13] The overall prevalence of AF is 2% to 4%, and increases with age (eg, approximately an 8% prevalence in patients greater than 65 years old). The prevalence of AF is expected to increase dramatically to an estimated 12 million by the year 2030. The general lifetime risk for AF in White people is 1 in 3 and 1 in 5 among Black people. Hypertension carries the highest risk of developing AF, followed by obesity, smoking, cardiac disease, diabetes, CKD, alcohol consumption, and sleep apnea.[13]

AF and AFl may present as a chronic, established tachycardia, an acute tachycardia, or a self-terminating, paroxysmal form. The following terms may be used to further define AF: first diagnosed AF (never diagnosed before, irrespective of its duration or symptoms), paroxysmal AF (terminates spontaneously or with intervention within 7 days of onset), persistent AF (duration longer than 7 days), long-standing persistent AF (duration longer than 12 months), and permanent AF (patient and provider jointly decide to stop attempts to restore or maintain SR).[14] AF is characterized by extremely rapid (atrial rate of 400-600 beats/min) and disorganized atrial activation. With this disorganized atrial activity, the contribution of synchronized atrial contraction (atrial kick) is lost, potentially decreasing forward cardiac output. Moreover, the impulses penetrate the AV conduction system in variable degrees resulting in an irregular activation of the ventricles and an irregularly irregular pulse (Fig. 40-6). The AV node will not conduct most of the supraventricular impulses, causing the ventricular response to be considerably slower than the atrial rate. It is sometimes stated that “AF begets AF,” that is, the arrhythmia tends to perpetuate itself. Long episodes are more difficult to terminate perhaps because of tachycardia-induced changes in atrial function (mechanical and/or electrical “remodeling”).

FIGURE 40-6

Electrocardiographic findings of common arrhythmias. (SVT, supraventricular tachycardia; AVRT, atrioventricular reentrant tachycardia; AF, atrial fibrillation.)

AFl occurs less frequently than AF but is similar in its precipitating factors, consequences, and medication therapy approach. This arrhythmia is characterized by rapid (atrial rate of 270 to 330 beats/min) but regular atrial activation. The slower and regular electrical activity results in a regular ventricular response that is in approximate factors of 300 beats/min (ie, 1:1 AV conduction = ventricular rate of 300 beats/min; 2:1 AV conduction = ventricular rate of 150 beats/min; 3:1 AV conduction = ventricular rate of 100 beats/min). AFl may be characterized as "typical" or "atypical." "Typical" flutter is the more common form, which involves the cavotricuspid isthmus. The characteristic "sawtooth" pattern of atrial activation is seen on the surface ECG (Fig. 40-6). The ventricular rate for "atypical" flutter can vary. There are times when a coarse AF can regularize into AFl and then degenerates into AF.

AF may result from multiple atrial reentrant loops (or wavelets), triggered, or abnormal automaticity, whereas AFl is caused by a single, dominant, reentrant substrate ("typical" AFl counterclockwise or clockwise circus movement in the right atrium around the tricuspid annulus). AF or AFl usually occurs in association with various forms of structural heart disease (SHD) that cause left atrial distension, including myocardial ischemia or infarction, hypertensive heart disease, valvular disorders such as mitral stenosis or mitral insufficiency, congenital abnormalities such as septal defects, dilated or hypertrophic cardiomyopathy, and obesity. Disorders that cause right atrial stretch and are associated with AF or AFl include acute pulmonary embolism and chronic lung disease resulting in pulmonary hypertension and right-sided heart failure. AF may also occur in association with states of high adrenergic tone such as thyrotoxicosis, surgery, alcohol withdrawal, sepsis, and excessive physical exertion. Other states in which patients are predisposed to episodes of AF are the presence of an accessory pathway and sinus node dysfunction (SND).

Patients with AF or AFl may experience the entire range of symptoms associated with other supraventricular tachycardias, although syncope as a presenting symptom is uncommon. Because left atrial kick is lost with the onset of AF, patients with HFrEF, HF with preserved ejection fraction (HFpEF) or critical valvular heart disease, particularly mitral stenosis, may develop worsening signs and symptoms of HF as they often depend on the contribution of their atrial kick to maintain an adequate cardiac output. Thromboembolic (TE) events resulting from atrial stasis, predominantly in the left atrial appendage (LAA), and poorly adherent mural thrombi are an additional complication of AF. The risk of stroke is increased fivefold in patients with AF.[14] Stroke can precede the onset of documented AF, probably because of undetected paroxysms prior to the onset of established AF. The risk of stroke significantly increases with age, with the annual attributable risk increasing from 1.5% in individuals 50 to 59 years of age to almost 24% in those 80 to 89 years of age.[15] The risk of stroke in patients with only AFl has been traditionally believed to be lower than AF. Yet, the same risk stratification scheme and antithrombotic recommendations used in patients with AF should also be applied to those with AFl.[14]

General Approach to Treatment

④ The Atrial Fibrillation Better Care (ABC) approach to the treatment of AF can be organized into several sequential goals: "A" Anticoagulation/Avoid stroke; "B" Better symptom management; "C" Cardiovascular and Comorbidity optimization. This approach improves outcomes and reduces cardiovascular events and health-related costs.[5] A review of the management of AF and AFl follows, organized according to the ABCs.

A—Anticoagulation/Avoid Stroke

Historically, warfarin has been the standard of care for stroke prevention in patients considered to be at moderate or high risk for stroke due to AF. However, while warfarin is undoubtedly effective in preventing strokes in patients with AF, its use is associated with several potential limitations, including a narrow therapeutic window, requirement for routine INR monitoring, food and drug interactions, and pharmacogenetic influences. Over the past decade, the Food and Drug Administration (FDA) has approved several oral antithrombotic therapies for stroke prevention in patients with AF not due to valvular heart disease (moderate-to-severe mitral stenosis or mechanical heart valve). These oral anticoagulant medications, commonly referred to as direct oral anticoagulants (DOAC), include the direct thrombin inhibitor, dabigatran, and the factor Xa inhibitors, apixaban, edoxaban, and rivaroxaban.

When initiating chronic antithrombotic therapy in patients with AF, the CHEST and American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommend assessing the patient's risk for stroke and bleeding before selecting the most appropriate regimen.[16,17] The CHA_2DS_2-VASc risk scoring system is used for stroke risk stratification in patients with AF.[16] CHA_2DS_2-VASc is an acronym for each of these risk factors as seen in Fig. 40-7. The points are added up, and the total score is then used to determine the most appropriate antithrombotic therapy for the patient. No antithrombotic therapy is recommended for males with a CHA_2DS_2-VASc score of 0 and females with a CHA_2DS_2-VASc score of 1, as these patients are considered to be at low risk for stroke.[16] For patients with one non-sex CHA_2DS_2-VASc stroke risk factor (ie, CHA_2DS_2-VASc score of 1 in males or 2 in females), oral anticoagulant therapy is suggested by the ACC/AHA and recommended by the CHEST guidelines over no antithrombotic therapy.[16,17] For patients with 2 or more non-sex CHA_2DS_2-VASc stroke risk factors (ie, CHA_2DS_2-VASc score of 2 or higher in males or 3 or higher in females), oral anticoagulant therapy is recommended. If anticoagulation is indicated, the patient's risk for bleeding should also be evaluated. There are several tools to assess bleeding risk, but the most predictive is the HAS-BLED score (Table 40-09).[16] A score of 3 or more is considered high-risk for bleeding. The score should be used to manage modifiable bleeding risk factors and increase surveillance for bleeding in patients with nonmodifiable risk factors.

TABLE 40-9

HAS-BLED Score to Predict Bleeding Risk in Patients with Atrial Fibrillation

Letter	Risk Factor	Points
H	Uncontrolled hypertension (systolic blood pressure >160 mm Hg)	1
A	Abnormal renal +/− hepatic function (dialysis, transplant, serum creatinine >2.26 mg/dL (200 µmol/L), cirrhosis, bilirubin >2× normal with AST/ALT/AP >3× normal)	1 point each
S	Stroke (ischemic or hemorrhagic)	1
B	Bleeding (history of major hemorrhage or anemia or severe thrombocytopenia)	1
L	Labile INR on warfarin (TTR <60%)	1
E	Elderly (>65 years old or extremely frail)	1
D	Drugs or alcohol use (concomitant use of antiplatelet or NSAID and/or ≥8 alcoholic drinks/week)	1 point each

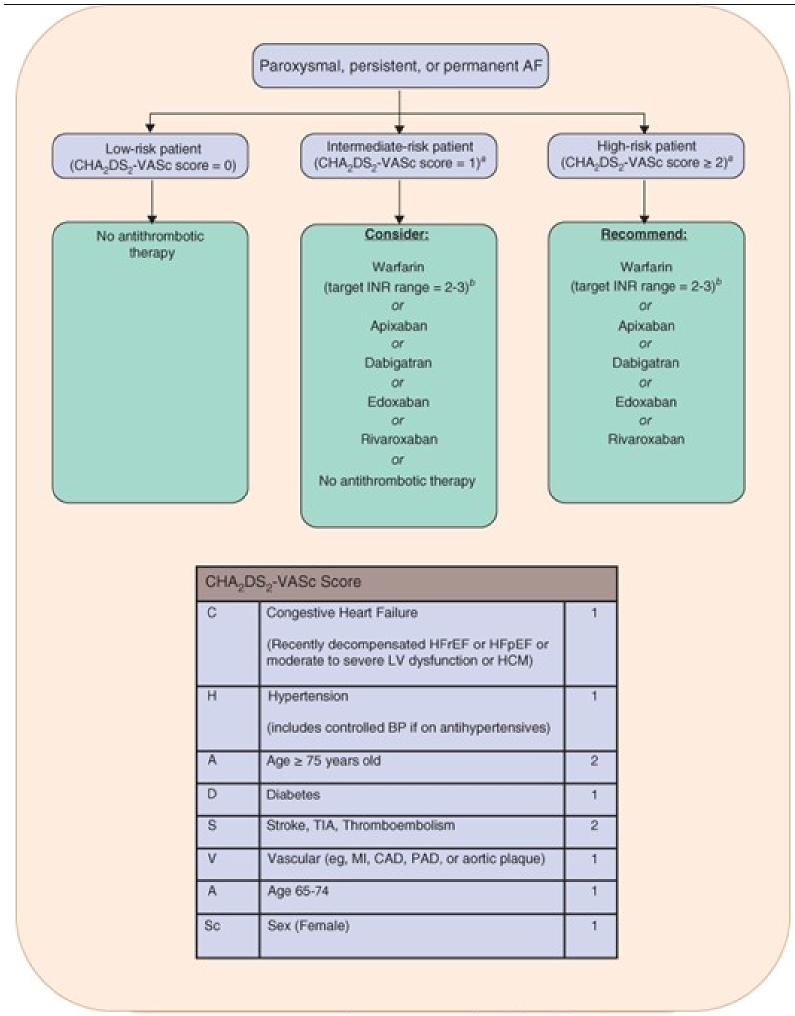
HAS-BLED score assesses a patient's 1-year risk of major bleeding when taking anticoagulants for atrial fibrillation. A score of 3 or greater is considered high risk for bleeding. The maximum score is 9. (AST, aspartate aminotransferase; ALT, alanine aminotransferase; AP, alkaline phosphatase; INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug; TTR, time in therapeutic range.)

FIGURE 40-7

Algorithm for the prevention of thromboembolism in atrial fibrillation.

[a] Score based on non-sex risk factors.

[b] The target INR for patients with prosthetic heart valves should be based on the type of valve that is present. (AF, atrial fibrillation; INR, international normalized ratio; MI, myocardial infarction; PAD, peripheral arterial disease.)



Paroxysmal, persistent, or permanent AF
Low-risk patient (CHA$_2$DS$_2$-VASc score = 0)
Intermediate-risk patient (CHA$_2$DS$_2$-VASc score = 1)^a
High-risk patient (CHA$_2$DS$_2$-VASc score ≥ 2)^a
No antithrombotic therapy
Consider:
Warfarin (target INR range = 2-3)^b or Apixaban or Dabigatran or Edoxaban or Rivaroxaban or No antithrombotic therapy
Recommend:
Warfarin (target INR range = 2-3)^b or Apixaban or Dabigatran or Edoxaban or Rivaroxaban

CHA$_2$DS$_2$-VASc Score		
C	Congestive Heart Failure (Recently decompensated HFrEF or HFpEF or moderate to severe LV dysfunction or HCM)	1
H	Hypertension (includes controlled BP if on antihypertensives)	1
A	Age ≥ 75 years old	2
D	Diabetes	1
S	Stroke, TIA, Thromboembolism	2
V	Vascular (eg, MI, CAD, PAD, or aortic plaque)	1
A	Age 65-74	1
Sc	Sex (Female)	1

The efficacy and safety of two dabigatran doses (110 mg and 150 mg twice daily) were compared with those of warfarin in patients with AF.[18] For the primary endpoint of stroke or systemic embolism, both dabigatran groups were shown to be noninferior to warfarin. Furthermore, the dabigatran 150-mg group was shown to be superior to warfarin in reducing this endpoint. The rate of major bleeding was similar between the dabigatran 150-mg and warfarin groups, while the rate of major bleeding was significantly lower in the dabigatran 110-mg group than in the warfarin group. The rate of intracranial hemorrhage (ICH) was significantly lower in both dabigatran groups than in the warfarin group. Even though the 110- and 150-mg dosing regimens of dabigatran were evaluated in this trial, only the 150-mg dose was initially approved by the FDA for AF. A lower 75-mg dose was also approved for patients with a CrCl of 15 to 30 mL/min (0.25 to 0.5 mL/s) even though this dose has not been evaluated in a randomized, prospective clinical trial in patients with AF; this dose has only pharmacokinetic data to support its use.[19] It is important to note that the trial excluded patients with a CrCl less than 30 mL/min (0.5 mL/s). A 110-mg dose of dabigatran has been approved for prophylaxis of venous thromboembolism in patients following hip replacement surgery. Although this dose has not been FDA-approved for stroke prevention in AF, the CHEST guidelines suggest using this dose (or apixaban or edoxaban) in patients with a history of or who are at high risk of bleeding.[16] Dabigatran is contraindicated in patients with mechanical heart valves because its use in this population has been associated with an increased risk of TE complications and bleeding.[20]

The efficacy and safety of rivaroxaban were compared with those of warfarin in patients with AF in the Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET AF).[21] In this study, patients were randomized to receive rivaroxaban 20 mg daily or adjusted-dose warfarin. For the primary endpoint of stroke or systemic embolism, rivaroxaban was shown to be noninferior to warfarin. The rate of major and nonmajor clinically relevant bleeding was similar between the rivaroxaban and warfarin groups. Significantly fewer ICHs occurred in the rivaroxaban group compared with the warfarin group.

The efficacy and safety of apixaban were compared with those of warfarin in patients with AF in the Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) trial.[22] Overall, apixaban was shown to be noninferior and superior to warfarin with regard to the primary endpoint of stroke or systemic embolism. The rate of major bleeding in this trial was significantly lower in the apixaban group than in the warfarin group. Additionally, significantly fewer ICHs occurred in the apixaban group compared with the warfarin group.

The efficacy and safety of edoxaban were compared with those of warfarin in patients with AF in the Effective Anticoagulation with Factor Xa Next Generation in Atrial Fibrillation-Thrombolysis in Myocardial Infarction (ENGAGE AF-TIMI) 48 trial.[23] In this study, patients were randomized to receive edoxaban 60 mg daily, edoxaban 30 mg daily, or adjusted-dose warfarin. Overall, both doses of edoxaban were shown to be noninferior to warfarin with regard to the primary endpoint of stroke or systemic embolism. However, the edoxaban 60-mg dosing regimen was also shown to be superior to warfarin with regard to this endpoint. The rate of major bleeding and the risk of ICH were significantly lower in both edoxaban groups than in the warfarin group. However, the risk of major gastrointestinal bleeding was significantly higher in the edoxaban 60-mg group, but significantly lower in the edoxaban 30-mg group when compared to the warfarin group.

Guidelines recommend therapy with a DOAC over warfarin.[16,17] However, it is essential that anticoagulant therapy be individualized for each patient, with consideration given to medication cost, insurance coverage, INR monitoring options, patient preference, drug interaction potential, anticipated medication adherence, and necessary follow-up. Specifically with warfarin, the target INR range should be 2 to 3 and the time in therapeutic range (TTR) should ideally be greater than 70%.[16] The TTR is an important metric when evaluating the efficacy of warfarin therapy as the risk of TE events, major bleeding, and death is lower in patients with a TTR of at least 65% compared to patients with a TTR of less than 65%.[24] The CHEST guidelines have recommended the use of the SAMe-TT$_2$R$_2$ score to assist in the identification of patients who are likely or not likely to achieve good anticoagulation control with warfarin (ie, TTR of at least 65%).[16] With this scoring system, patients with AF are given two points each if they use tobacco or are of a non-white race. Patients are given one point each for being female, being younger than 60 years of age, having at least two of the specified medical conditions (hypertension, diabetes, CAD/MI, congestive HF, previous stroke, pulmonary disease, hepatic disease, or renal disease), or receiving treatment with a medication that interacts with warfarin. SAMe-TT$_2$R$_2$ is an acronym for each of these risk factors. Once the points for this scoring system are added up, a score of 0 to 2 suggests that patients are likely to achieve a TTR of at least 65%. Patients with a score of more than 2 are less likely to achieve a TTR of at least 65% and should be educated on strategies that could improve their TTR including more frequent INR monitoring and medication reviews, adherence counseling, and dietary guidance. Alternatively, these patients could be considered for DOAC therapy. Additionally, if a patient has previously taken warfarin, the time that his/her INR has been within the therapeutic range should also be considered before making the decision to switch the patient to a DOAC.

If a patient is unable to maintain a therapeutic INR while on warfarin, therapy with a DOAC is recommended. Strict adherence with the DOACs is important because missing a single dose could result in an increased risk of TE events.[25] If treatment with warfarin must be temporarily interrupted for the patient to undergo a medical procedure, coverage with a parenteral anticoagulant (eg, unfractionated heparin, low molecular weight heparin [LMWH]) should be considered in patients with a high risk of stroke and/or have a mechanical heart valve. Moreover, warfarin is the anticoagulant of choice for patients with moderate to severe mitral stenosis or a mechanical heart valve; the INR should be based on the type and location of the valve placed. Dabigatran, edoxaban, and rivaroxaban should be avoided in patients with a CrCl less than 15 mL/min (0.25 mL/s). In this particular population, anticoagulant options are warfarin and apixaban. Edoxaban should also be avoided in patients with a CrCl greater than 95 mL/min (1.58 mL/s) because of the potential for reduced efficacy.

Although it was previously an acceptable practice to discontinue antithrombotic therapy 4 weeks after successful cardioversion (with the belief that a patient's risk for thromboembolism had abated since he/she was in SR), data from the RACE and AFFIRM trials strongly suggest that patients with AF and other risk factors for stroke continue to be at risk for stroke even when maintained in SR.[26,27] It is possible that these patients may be having undetected episodes of paroxysmal AF, placing them at risk for stroke. Consequently, the decision regarding chronic antithrombotic therapy should be based on a patient's risk for stroke using the CHA$_2$DS$_2$-VASc scoring system.[14]

Should a patient have an increased risk of stroke, but have a contraindication to long-term anticoagulation, a LAA occluder may be an alternative.[5,14,17] The Watchman, the only FDA-approved device, is deployed into the left atrial appendage and designed to conform to the anatomy of the LAA, permanently sealing it off and reducing the risk of emboli. Although postimplantation antithrombotic practice patterns vary, patients should initiate aspirin the day before the procedure and an oral anticoagulant upon implantation. If an adequate seal has been formed at 45 days postimplant, oral anticoagulation should be discontinued, aspirin should be continued, and a $P2Y_{12}$ inhibitor should be started. At 6 months postimplant, the $P2Y_{12}$ inhibitor is stopped while aspirin is continued life long.

B—Better Symptom Management

Should patients receive rate control (regulate only the ventricular rate and remain in AF) or rhythm control (restoring and maintaining normal sinus rhythm)? Six landmark clinical trials have compared the efficacy of rate control and rhythm control treatment strategies in patients with AF.[26-31] The Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM) trial is the largest rate control versus rhythm control study conducted to date in patients with AF.[27] In this trial, patients with AF and at least one risk factor for stroke were randomized to either a rate control or a rhythm control group. Rate-control treatment involved AV nodal blocking medications (digoxin, β-blockers, and/or non-DHP CCBs) first, and then nonpharmacologic treatment (AV nodal ablation with pacemaker implantation), if necessary. All patients in this group were anticoagulated. In the rhythm control group, class I or III AADs were used to maintain SR. The choice of AAD therapy was left up to each patient's physician. By the end of the trial, more than 60% of patients had received at least one trial of amiodarone, and approximately 40% of patients had received at least one trial of sotalol. In the rhythm control group, anticoagulation was encouraged but could be discontinued if SR had been maintained for at least 4 weeks. Overall mortality was not statistically different between the two strategies. However, patients in the rhythm-control group were significantly more likely to be hospitalized or experience an adverse drug reaction. The results of the other four trials were consistent with those of the AFFIRM trial.[26,28-30] In addition, a meta-analysis of these data demonstrated no significant difference in overall mortality between rate control and pharmacological rhythm control strategies, which persisted even when the results from the AFFIRM trial were excluded from this analysis.[32]

Collectively, these trials demonstrate that a rate control strategy is a viable alternative to a rhythm control strategy in patients with persistent AF. However, only a small proportion of patients enrolled in these trials had HFrEF. Thus, a trial was conducted to specifically evaluate the safety and efficacy of rate control and rhythm control strategies in patients with HFrEF.[31] Consistent with other rate control versus rhythm control studies, no significant difference in the primary endpoint of death from cardiovascular (CV) causes was observed between treatment groups. Though not statistically significant, patients in the rhythm control group tended to have more hospitalizations, primarily due to repeated cardioversions and adjustment of AAD therapy. It is important to note that the results of this trial should not be applied to patients with HFpEF. Together, these trials suggest that a pharmacological rhythm control strategy does not confer any advantage over a rate control strategy in patients with AF, with or without HFrEF.

④ Clearly, these important findings temper the old approach of aggressively attempting to maintain SR. Because a rhythm control strategy does not offer any significant advantage over a rate control strategy in the management of patients with AF, the decision to utilize one strategy over another is primarily driven by the goal of improving a patient's quality of life (Table 40-10).

TABLE 40-10

Considerations for Selecting a Rate-Control Versus Rhythm-Control Strategy in Patients with Atrial Fibrillation

Rate-Control	Rhythm-Control
No or minimal symptoms	Paroxysmal or persistent AF
Treatment of choice for permanent AF	Symptomatic despite adequate rate control
	Hemodynamically unstable
	Exacerbating heart failure
	Tachycardia-mediated cardiomyopathy
	Other factors • Younger age • First episode of AF • Patient preference

AF, atrial fibrillation.

Rate Control

Once the decision has been made to rate control a patient, the next important question is: What defines "adequate" ventricular rate control? A lenient rate control strategy targeting a resting heart rate less than 110 beats/min is recommended for asymptomatic patients with a preserved LV systolic function (LVEF greater than 40% [0.40]).[14,33] In patients who are symptomatic or have LV systolic dysfunction (LVEF less than or equal to 40% [0.40]), a stricter rate control approach targeting a resting heart rate less than 80 beats/min should be considered.

The selection of an AV nodal-blocking medication to control ventricular rate is primarily based on the patient's LV function.[14] In patients with preserved LV function or in patients with stable HFpEF, a β-blocker or non-DHP CCB (diltiazem or verapamil) is preferred over digoxin because of their relatively quick onset and maintained efficacy during exercise. When adequate ventricular rate control cannot be achieved with one of these medications, the addition of digoxin may result in an additive lowering of the heart rate. However, digoxin tends to be ineffective for controlling ventricular rate under conditions of increased sympathetic tone (ie, surgery, thyrotoxicosis) because it slows AV nodal conduction primarily through vagotonic mechanisms. Verapamil and diltiazem should be avoided in patients with HFrEF (LVEF less than or equal to 40% [0.40]) because of their potent negative inotropic effects.[14] Instead, β-blockers and digoxin are preferred. Specifically, in patients with NYHA class II or III HF, β-blockers should be considered over digoxin because of their survival benefits in patients with HFrEF. If patients are having an episode of decompensated HF (NYHA class IV), digoxin is preferred as first-line therapy to achieve ventricular rate control because of the potential for worsening HF symptoms with the initiation and subsequent titration of β-blocker therapy. Several analyses have associated digoxin with a significant increase in the risk of mortality in patients with AF.[34] The risk is highest when serum digoxin concentrations are 1.2 ng/mL (mcg/L; 1.5 nmol/L) or greater.[35]

If adequate ventricular rate control during rest and exercise cannot be achieved with β-blockers, non-DHP CCBs, and/or digoxin in patients with normal or depressed LV function, amiodarone can be used as an alternative therapy to control the heart rate (Table 40-11). However, clinicians should be aware that the use of amiodarone for controlling ventricular rate may also stimulate the conversion of AF to SR and place the patient at risk for a TE event, especially if the AF has persisted for at least 48 hours or is of unknown duration.

TABLE 40-11

Evidence-Based Pharmacologic Treatment Recommendations for Controlling Ventricular Rate, Restoring Sinus Rhythm, and Maintaining Sinus Rhythm in Patients with Atrial Fibrillation

Treatment Recommendations	ACC/AHA Guideline Recommendation
Ventricular rate control (acute setting)	
In the absence of an accessory pathway, an IV β-blocker or IV non-DHP CCB is recommended for patients without HF.	Class I
In the absence of an accessory pathway, IV digoxin or IV amiodarone is recommended to control the ventricular rate in patients with HF.	Class I
In the absence of an accessory pathway, an IV β-blocker is recommended to control the ventricular rate in patients with stable HFrEF.	Class I
In the absence of an accessory pathway, an IV non-DHP CCB is recommended to control the ventricular rate in patients with stable HFpEF.	Class I
In the absence of an accessory pathway, IV amiodarone is recommended to control the ventricular rate in critically ill patients.	Class IIa
IV amiodarone can be useful to control the ventricular rate when other measures are unsuccessful or contraindicated.	Class IIa
Digoxin, non-DHP CCBs, or IV amiodarone should not be used in patients with an accessory pathway.	Class III
IV β-blockers or IV non-DHP CCBs are not recommended in patients with decompensated HF.	Class III
Ventricular rate control (chronic setting)	
An oral β-blocker or non-DHP CCB is recommended to control the ventricular rate in patients with paroxysmal, persistent, or permanent AF.	Class I
An oral β-blocker or non-DHP CCB is recommended to control the ventricular rate in patients with persistent or permanent AF and compensated HFpEF.	Class I
Digoxin is effective for controlling resting heart rate in patients with HFrEF.	Class I
A combination of digoxin and a β-blocker is reasonable to control resting and exercise heart rate in patients with HFrEF.	Class IIa
A combination of digoxin and a non-DHP CCB is reasonable to control resting and exercise heart rate in patients with HFpEF.	Class IIa
Oral amiodarone can be used when the ventricular rate cannot be adequately controlled at rest and during exercise with an oral β-blocker, non-DHP CCB, and/or digoxin.	Class IIb
Oral non-DHP CCBs and dronedarone are not recommended to control the ventricular rate in patients with decompensated HF.	Class III
Dronedarone should not be used to control the ventricular rate in patients with permanent AF.	Class III
Restoration of sinus rhythm	
In the absence of contraindications, flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF.	Class I

Oral amiodarone is a reasonable option for pharmacologic cardioversion of AF.	Class IIa
The "pill-in-the-pocket" approach with flecainide or propafenone can be used to terminate persistent AF on an outpatient basis once the treatment has been used safely in the hospital, in patients without sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or SHD (*Note*: AV node must be adequately blocked with β-blocker or non-DHP CCB therapy before initiating this therapy).	Class IIa
Dofetilide should not be initiated on an outpatient basis.	Class III
Maintenance of sinus rhythm	
The following AADs are recommended for maintaining SR, depending on underlying SHD and other comorbidities: amiodarone, dofetilide, dronedarone, flecainide, propafenone, and sotalol.	Class I
Because of its potential toxicities, amiodarone should only be used after consideration of its risks and when other agents have failed or are contraindicated.	Class I
The risk of the AAD, including proarrhythmia, should be considered before initiating treatment with that medication.	Class I
Antiarrhythmic therapy can be useful for maintaining SR for the treatment of tachycardia-induced cardiomyopathy.	Class IIa
It may be reasonable to continue current AAD therapy in the setting of infrequent, well-tolerated recurrences of AF when the medication has reduced the frequency or symptoms of AF.	Class IIb
An AAD should not be continued when the AF becomes permanent.	Class III
Dronedarone should not be used in patients with class III or IV HF or patients who have had an episode of decompensated HF in the last 4 weeks.	Class III

AAD, antiarrhythmic medication; ACC, American College of Cardiology; AF, atrial fibrillation; AHA, American Heart Association; AV, atrioventricular; CCB, calcium channel blocker; DHP, dihydropyridine; HF, heart failure; HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced ejection fraction; HRS, Heart Rhythm Society; IV, intravenous; SHD, structural heart disease; SR, sinus rhythm.

Data from Reference 36.

Rhythm Control

In those whose decision has been made to restore SR, one must consider that this very act (regardless of whether an electrical or pharmacologic method is chosen) places the patient at risk for a TE event. The heightened risk is because the return of SR restores effective contraction in the atria, which may dislodge poorly adherent thrombi. Administering anticoagulant therapy prior to cardioversion not only prevents clot growth and the formation of new thrombi but also allows existing thrombi to become organized and well adherent to the atrial wall. It is a generally accepted principle that the risk of thrombus formation and a subsequent embolic event increases if the duration of the AF exceeds 48 hours. Therefore, it is vital for clinicians to estimate the duration of the patient's AF so that appropriate anticoagulant therapy can be administered prior to cardioversion if needed.

For patients undergoing elective cardioversion (electrical or pharmacologic) for AF lasting at least 48 hours or for an unknown duration, guidelines recommend that therapeutic anticoagulation with warfarin or DOAC should be given for at least 3 weeks before cardioversion is performed; this recommendation applies to patients regardless of their CHA_2DS_2-VASc score.[16,37] If 3 weeks of therapeutic oral anticoagulant therapy is not feasible in these patients, a screening transesophageal echocardiogram (TEE) can be performed prior to cardioversion to evaluate for the presence of thrombus in the heart chambers (particularly the atria or atrial appendage). Overall, there is no difference in the efficacy and safety between DOACs and warfarin in patients undergoing TEE-guided cardioversion.[38]

If cardioversion is successful (ie, patient is now in SR), therapeutic anticoagulation with warfarin (INR target range 2 to 3) or a DOAC should be continued for at least 4 weeks, regardless of the patient's baseline risk of stroke.[16,37] The reason for continuing anticoagulation for this additional 4-week time period is that after restoration of SR, full atrial contraction does not occur immediately. Rather, it returns gradually to a maximum contractile force over a 3- to 4-week period. Decisions regarding long-term antithrombotic therapy after this 4-week period should be based on the patient's risk for stroke and not on whether the patient is in SR. If a thrombus is seen on TEE, cardioversion should not be performed and the patient should be anticoagulated for another 4 to 12 weeks.[16]

In patients with AF that is less than 48 hours in duration, a prolonged period of anticoagulation prior to cardioversion is unnecessary because there has not been sufficient time to form atrial thrombi. However, an oral anticoagulant, LMWH or unfractionated heparin should be started as soon as possible.[5,16,37]

After anticoagulation needs and/or TEE have been addressed, the process of restoring SR can be considered. There are two methods of restoring SR in patients with AF or AFl: pharmacologic cardioversion and DCCV. The decision to use either of these methods is generally based on clinical preference and the hemodynamic stability of the patient. In situations of hemodynamic instability (eg, severe hypotension, angina, or pulmonary edema), direct current cardioversion is indicated as first-line therapy in an attempt to immediately restore SR (without regard to the risk of thromboembolism). The disadvantages of pharmacologic cardioversion are the risk of significant adverse drug reactions (eg, drug-induced TdP), the potential for drug-drug interactions (eg, digoxin–amiodarone), and the lower efficacy of AADs when compared with DCCV. The advantages of DCCV are that it is quick and more often successful (80% to 90% success rate) compared to pharmacologic cardioversion. The disadvantages of DCCV are the need for periprocedural sedation/anesthesia and the risk (albeit small) of serious complications such as sinus arrest or ventricular arrhythmias.

Nonetheless, despite the relatively high success rate associated with DCCV, clinicians and patients may elect to use AADs first, and then resort to DCCV if these medications fail. Pharmacologic cardioversion appears to be most effective when initiated within 7 days after the onset of AF.[14] There is relatively strong evidence for the efficacy of class III pure I_K blockers (ibutilide and dofetilide), the class Ic AADs (flecainide and propafenone), and amiodarone (oral or IV) for cardioversion of AF.[14] Class Ia AADs have limited efficacy or have not been adequately studied in this setting. Sotalol is not effective for cardioversion of paroxysmal or persistent AF. Single, oral loading doses of propafenone (body weight greater than 70 kg: 600 mg; less than 70 kg: 450 mg) and flecainide (body weight greater than 70 kg: 300 mg; less than 70 kg: 200 mg) are effective compared with placebo for conversion of recent-onset AF and have been incorporated into the "pill-in-the-pocket" approach endorsed by treatment guidelines.[14,39] With this method, patient-controlled, self-administration of a single, oral loading dose of flecainide or propafenone in the outpatient setting is relatively safe and effective for the termination of recent-onset AF in the absence of sinus or AV node dysfunction, bundle-branch block, or SHD.[39] This approach should be considered in patients who have previously been successfully cardioverted with these medications on an inpatient basis.

Overall, when considering pharmacologic cardioversion, the selection of an AAD should be based on whether the patient has SHD (eg, LV dysfunction, CAD, valvular heart disease, LV hypertrophy).[14] In the absence of any type of SHD, the use of a single, oral loading dose of flecainide or propafenone is a reasonable approach for cardioversion. Ibutilide can also be used as an alternative in this patient population; however, the use of this agent is restricted to a monitored setting in the hospital because it requires QT interval monitoring. In patients with underlying SHD, flecainide, propafenone, and ibutilide should be avoided because of the increased risk of proarrhythmia; amiodarone or dofetilide should be used instead. Although amiodarone can be administered safely on an outpatient basis because of its low proarrhythmic potential, dofetilide therapy can only be initiated in the hospital (for QT interval monitoring and assessment of renal function). Additionally, a patient's ventricular rate should be adequately controlled with AV nodal blocking medications prior to administering a class Ic AAD for cardioversion. The class Ic AADs may paradoxically increase ventricular response. The most likely mechanism for this effect is that by slowing atrial conduction, the class Ic AADs decrease the number of impulses reaching the AV node. Consequently, the AV node paradoxically allows more impulses to gain entrance to the ventricular conduction system, thereby increasing ventricular rate.

Class Ic or III AADs are reasonable to consider to maintain patients in SR (Table 40-12).[14] The role of the class Ia AADs for maintenance of SR has been deemphasized compared with the class Ic and III AADs. While a systematic review of AADs for the maintenance of SR after cardioversion in patients with AF demonstrated that AF recurrences were significantly reduced with the use of class Ia, Ic, and III AADs, mortality was significantly increased with the class Ia medications.[40] The class Ic AADs, flecainide and propafenone, are effective for maintaining SR. However, because of the increased risk for proarrhythmia, these medications should be avoided in patients with SHD.

TABLE 40-12

Guidelines for Selecting Antiarrhythmic Medication Therapy to Maintain Sinus Rhythm in Patients with Recurrent Paroxysmal or Recurrent Persistent Atrial Fibrillation

No structural heart disease[a] (absence of heart failure, coronary artery disease, or significant LVH)

First line[b]: dofetilide, dronedarone, flecainide, propafenone, or sotalol

Second line[c]: amiodarone

Heart failure[a]

First line[b]: amiodarone or dofetilide

Second line: catheter ablation

Coronary artery disease[a]

First line[b]: dofetilide, dronedarone,[d] or sotalol[d]

Second line[c]: amiodarone

LVH, left ventricular hypertrophy.

[a] Medications are listed alphabetically and not in order of suggested use.

[b] Catheter ablation may also be considered first-line therapy in select patients with paroxysmal atrial fibrillation.

[c] Catheter ablation may also be considered when patients are refractory or intolerant to at least one antiarrhythmic medication.

[d] Should only be used in this situation if the patient has normal left ventricular systolic function.

Although all oral class III AADs have demonstrated efficacy in preventing AF recurrences, amiodarone is clearly the most effective agent and the most frequently used AAD despite its potential for causing significant organ toxicity.[41] The superiority of amiodarone over other AADs for maintaining patients in SR has been demonstrated in a number of clinical trials. Amiodarone was significantly more effective than sotalol or propafenone in maintaining SR in patients with persistent or paroxysmal AF.[42] Amiodarone was also found to be significantly more effective than sotalol at maintaining SR in all patient subgroups, except for those with CAD where the efficacy of these two medications was comparable.[43] Furthermore, amiodarone appears to be the most effective AAD in maintaining SR.[44]

Although sotalol is not effective for the conversion of AF, it is an effective medication for maintaining SR. Sotalol appears to be at least as effective as propafenone in preventing recurrences of AF.[42] However, treatment with sotalol is associated with TdP. Because TdP occurs primarily with higher doses of sotalol, it may be easier to predict and avoid. Nonetheless, sotalol may increase mortality in patients with AF.[45]

Dofetilide is effective in preventing AF recurrences but has not been directly compared with either amiodarone or sotalol. In a large, multicenter trial, dofetilide was more effective than placebo in maintaining SR (approximately 35% to 50% at 1 year).[46] The efficacy of dofetilide for maintenance of SR has also specifically been demonstrated in patients with HFrEF.[47] Like sotalol and quinidine, dofetilide also has significant potential to cause TdP (in a dose-related fashion).

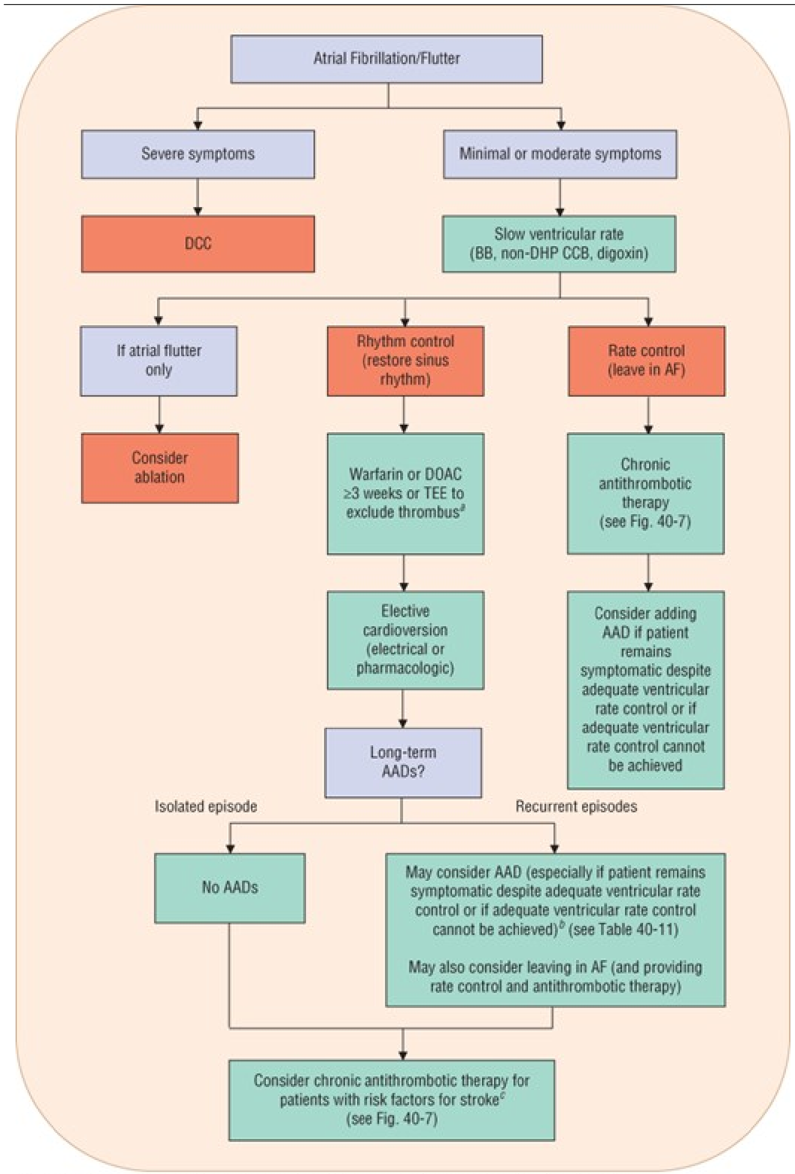
In two similarly designed trials, dronedarone was more effective than placebo in maintaining SR in patients with paroxysmal or persistent AF or AFl.[48] In another trial, the use of dronedarone in patients with persistent or paroxysmal AF or AFl was associated with significantly fewer hospitalizations due to CV events or death when compared with placebo.[49] In another study, dronedarone was shown to be significantly less effective than amiodarone in reducing AF recurrences.[50] However, tolerability was significantly better in the dronedarone group than the amiodarone group as evidenced by higher rates of premature medication discontinuation due to adverse events in the amiodarone group.[50] Most recently, a trial that enrolled patients with permanent AF and risk factors for major vascular events was terminated prematurely after significantly more patients in the dronedarone group died (primarily from CV causes), or hospitalized for HF, or suffered a stroke compared with the placebo group.[51] Based on the results of this trial, dronedarone is contraindicated (black box warning) in patients with permanent AF. One study evaluated the safety and efficacy of dronedarone to prevent death and heart failure hospitalizations in patients with NYHA class III or IV HFrEF (presumably due to decreasing arrhythmia occurrence).[52] This trial was prematurely terminated because all-cause mortality (primarily due to worsening HF) was significantly higher in the dronedarone group compared with the placebo group. Consequently, dronedarone is contraindicated (black box warning) in advanced HF (NYHA class IV or NYHA class II or III with a recent hospitalization for decompensated HF).

Overall, the selection of an AAD to maintain SR should be primarily based on whether the patient has SHD.[14] However, other factors, including renal and hepatic function, concomitant disease states and medications, and the AAD's side effect profile also need to be considered. Dofetilide, dronedarone, flecainide, propafenone, or sotalol should be considered initially for those patients with no underlying SHD because these medications have the most optimal long-term safety profile in this setting.[14] However, amiodarone could be used as an alternative therapy if the patient fails or does not tolerate one of these initial AADs. In the presence of SHD, flecainide and propafenone should be avoided because of the risk of proarrhythmia. For those patients with HFrEF (LVEF less than or equal to 40% [0.40]), amiodarone or dofetilide should be considered the AADs of choice. Only amiodarone and dofetilide have been shown to be mortality-neutral in patients with AF and HFrEF. Both dronedarone and sotalol should be avoided in patients with HFrEF because of the risk for increased mortality (dronedarone) or worsening HF (dronedarone and sotalol). In patients with CAD, dofetilide, dronedarone, or sotalol can be used initially. Amiodarone could be used as an alternative therapy if the patient fails or does not tolerate one of these initial AADs. The presence of LV hypertrophy may predispose the myocardium to proarrhythmic events. Because of their low proarrhythmic potential, amiodarone or dronedarone should be considered first-line AAD therapy in these patients.

Figure 40-8 shows an algorithm for the management of AF and AFl.

FIGURE 40-8

Algorithm for the treatment of AF and AFl. [a]If AF is less than 48 hours in duration, anticoagulation prior to cardioversion is unnecessary; initiate anticoagulation with unfractionated heparin, a low-molecular-weight heparin, apixaban, dabigatran, edoxaban, or rivaroxaban as soon as possible either before or after cardioversion for stroke prevention (this anticoagulant regimen or no antithrombotic therapy may be considered in low-risk patients). [b]Ablation may be considered for patients who fail or do not tolerate at least one AAD or as first-line therapy (before AAD therapy) for select patients with recurrent symptomatic paroxysmal AF or any classification of AF and heart failure with reduced left ventricular ejection fraction. [c]Chronic antithrombotic therapy should be considered in all patients with AF and risk factors for stroke regardless of whether or not they remain in sinus rhythm. (AAD, antiarrhythmic medication; AF, atrial fibrillation; AFl, atrial flutter; BB, beta-blocker; non-DHP CCB, non-dihydropyridine calcium channel blocker; DCCV, direct current cardioversion; DOAC, direct oral anticoagulant; TEE, transesophageal echocardiogram.)



Atrial Fibrillation/Flutter
Severe symptoms
Minimal or moderate symptoms
DCC
Slow ventricular rate (BB, non-DHP CCB, digoxin)
If atrial flutter only
Rhythm control (restore sinus rhythm)
Rate control (leave in AF)
Consider ablation
Warfarin or DOAC ≥3 weeks or TEE to exclude thrombus[a]
Chronic antithrombotic therapy (see Fig. 40-7)
Elective cardioversion (electrical or pharmacologic)
Consider adding AAD if patient remains symptomatic despite adequate ventricular rate control or if adequate ventricular rate control cannot be achieved
Long-term AADs?
Isolated episode
Recurrent episodes
No AADs
May consider AAD (especially if patient remains symptomatic despite adequate ventricular rate control or if adequate ventricular rate control cannot be achieved)[b] (see Table 40-11)
May also consider leaving in AF (and providing rate control and antithrombotic therapy)
Consider chronic antithrombotic therapy for patients with risk factors for stroke[c] (see Fig. 40-7)

Nonpharmacologic forms of therapy, designed to maintain SR, are becoming increasingly popular treatment options for patients with AF or AFl. For patients who have "typical" AFl, not associated with concurrent AF, ablation of the reentrant substrate with radiofrequency current is highly effective (more than 90%) and should be first-line treatment of AFl to prevent recurrences.[53] Catheter ablation for patients with AF is much more technically difficult for a variety of reasons, including the lack of a single, identifiable, and ablatable reentrant focus (as in AFl). Patients with AF have been found to have arrhythmogenic foci that occur in atrial tissue near and within the pulmonary veins. The ablation procedure most commonly used is a pulmonary vein isolation (PVI) ablation, where the foci originating in these areas are abolished by locally delivering heat (radiofrequency energy) or freezing the tissue (cryoablation). Historically, PVI ablation was often considered last-line therapy for patients who had failed all AADs, including amiodarone. However, in some trials, the use of PVI ablation in patients with AF has been associated with a significant reduction in recurrent episodes of AF and an improvement in quality of life when compared with AAD therapy.[54,55] In patients with AF and concomitant HFrEF who did not respond to, were intolerant of, or were unwilling to take AADs, the use of PVI ablation has been associated with a significant reduction in all-cause mortality or hospitalization for worsening HF.[56] There is also evidence to suggest that this procedure may be superior to AADs as first-line therapy of symptomatic AF.[57,58] Moreover, ablation is an appropriate option for patients with tachycardia-induced cardiomyopathy. Controlling comorbidities (ie, OSA, obesity, HTN) highly contributes to the success of maintaining normal sinus rhythm post ablation. This procedure is not without risks, as major complications, such as pulmonary vein stenosis, TE events, cardiac tamponade, and new AFl, have been reported in 4.5% of patients.[59]

C—Cardiovascular and Comorbidity Optimization

Cardiovascular burden and comorbidities, such as obesity, hypertension, diabetes, and sleep apnea, play a role in atrial structural and electrical remodeling; thus, the development of AF.[5] Weight loss can reduce AF episodes and reoccurrence after ablation. Furthermore, weight loss can reduce blood pressure, Hgb A1C, and cholesterol, which leads to better cardiovascular health. Other lifestyle interventions a patient should engage in are abstaining from alcohol and incorporating physical activity, except for endurance training, as this can precipitate AF.

Patients with hypertension have a 1.7-fold higher risk of AF than a patient with normal blood pressure and should be treated to a goal blood pressure of ≤130/80 mm Hg.[5] Patients with diabetes have a twofold higher prevalence of AF than those without diabetes. Moreover, diabetes places patients at a higher risk for stroke. Roughly 50% of patients with AF have sleep apnea. When managed with continuous positive airway pressure, the recurrence of AF may be ameliorated. Controlling these disease states reduces a patient's risk of developing AF, the number of occurrences the patient experiences, and the success of rhythm control management.

Paroxysmal Supraventricular Tachycardia

⑤ PSVT generated by reentrant mechanisms includes AV nodal reentry (ie, AVNRT), AV reentry incorporating an accessory pathway (ie, AVRT), SA nodal reentry, and intra-atrial reentry. AVNRT and AVRT are, by far, the most common of these tachycardias.

AVNRT is usually seen in middle-aged adults without heart disease and more than 60% of cases occur in females.[60] The ventricular rate can range from 110 beats/min to more than 250 beats/min. This arrhythmia can spontaneously occur or be provoked by exertion, coffee, tea, or alcohol. Patients generally tolerate AVNRT hemodynamically; however, many are highly symptomatic.[53]

The underlying substrate of AVNRT is the functional division of the AV node into two (or more) longitudinal conduction pathways or "dual" AV nodal pathways.[61] There are not two distinct anatomic pathways inside the AV node itself; rather, it is likely that a fan-like network of perinodal fibers inserts into the AV node and represents the second pathway. The pathways possess key differences in conduction characteristics: one is a fast-conducting pathway with a relatively long refractory period (fast pathway) and the other is a slower-conducting pathway with a shorter refractory period (slow pathway). The presence of dual pathways does not necessarily imply that the patient will have clinical PSVT. In fact, it is estimated that between 10% and 50% of patients have discernible dual pathways, but the incidence of AVNRT is considerably lower.[61] Sustenance of the tachycardia depends on the critical electrophysiologic discrepancies and the ability of one pathway (usually the slow) to allow repetitive antegrade conduction, and the ability of the other pathway (usually the fast) to allow repetitive retrograde conduction. During SR, a patient with dual pathways conducts the impulses antegrade through both pathways but reaches the distal common pathway first through the fast AV nodal route and continues to depolarize the ventricles in an antegrade direction (Fig. 40-9).

FIGURE 40-9

Reentry mechanism of dual AV nodal pathway PSVT. (*A*) Sinus rhythm: the impulse travels from the atrium through the fast pathway, F, and then to the distal common pathway and the His-Purkinje system (*His*). The impulse also travels through the slow pathway, S, but is stopped when refractory tissue is encountered. (*B*) Dual AV nodal reentry: a critically timed premature impulse, *, is stopped in the fast pathway, F (because of prolonged refractoriness) but is able to travel antegrade down the slow pathway, S, and retrograde through the fast pathway. (AV, atrioventricular; PSVT, paroxysmal supraventricular tachycardia.)

The mechanism behind AVNRT may occur by the following sequence of events. The occurrence of a properly timed premature atrial impulse penetrates the AV node but is blocked in the fast pathway that is still refractory from the previous beat. However, the slow pathway, which has a shorter refractory period, permits antegrade conduction of the premature impulse. By the time the impulse has reached the distal common pathway, the fast pathway has recovered its excitability and now will permit retrograde conduction. The impulse then reaches the common proximal pathway, reenters the slow pathway, and the tachycardia is initiated. This reentrant circuit that does not require atrial or ventricular tissue; it is completed within the AV node. The common form of this tachycardia uses the slow pathway for antegrade conduction and the fast pathway for retrograde conduction; an uncommon form exists in which the reentrant impulse travels in the opposite direction.

AVRT is generally seen in young adults, and like AVNRT, it is generally well tolerated. However, it can be less benign than AVNRT as it can cause syncope. AVRT depends on the presence of an accessory pathway that bypasses the normal AV conduction pathway. Several different types of accessory pathways have been described, depending on the specific anatomic areas they connect (eg, AV or nodoventricular tracts). During SR (Fig. 40-10), patients with an accessory pathway that can conduct antegrade depolarize the ventricles simultaneously through both the AV nodal and accessory pathway, causing ventricular preexcitation and creating a fusion pattern on the early portion of the QRS complex (known as a delta wave). Patients may have an accessory pathway that is not evident on ECG, which is referred to as a "concealed" accessory pathway. These concealed accessory pathways are often incapable of antegrade conduction and can only accept electrical stimulation in a retrograde fashion. The electrocardiographic expression of a delta wave depends on the location of the accessory pathway, the distance from the wave front of sinus activation, and the conduction characteristics of the various structures involved. Similar to patients with dual AV nodal pathways, not all patients with an accessory AV pathway are capable of having clinical PSVT, characterized as Wolff-Parkinson-White (WPW) syndrome.

FIGURE 40-10

Reentry mechanism for AV accessory pathway PSVT in Wolff-Parkinson-White syndrome. (*A*) Sinus rhythm: the impulse travels from the atrium to the ventricle by two pathways—the AV node and an accessory bypass pathway. (*B*) AV reentry: a critically timed premature impulse (*) is stopped in accessory pathway (because of prolonged refractoriness) but travels antegrade through the AV node and retrograde through accessory pathway. (AV, atrioventricular; His, His-Purkinje system; LB, left bundle branch; PSVT, paroxysmal supraventricular tachycardia; RB, right bundle branch; SA, sinoatrial.)

⑥ WPW syndrome can occur as orthodromic AVRT, antidromic AVRT, and/or AF. AVRT usually occurs by the following sequence of events. Analogous to AVNRT, two pathways (eg, the normal AV nodal pathway and the accessory AV pathway) exist that have different electrophysiologic characteristics. The AV nodal pathway usually has a relatively slower conduction velocity and shorter refractory period, and the accessory pathway has a faster conduction velocity and a longer refractory period. A critically timed premature atrial impulse may be blocked in the accessory pathway because this area is still refractory from the previous sinus beat. However, the AV nodal pathway, with a relatively shorter refractory period, may accept antegrade conduction of the premature atrial impulse. Meanwhile, the accessory pathway may recover its excitability and now allow retrograde conduction. A macroreentrant tachycardia is thereby initiated in which the antegrade pathway is the AV nodal pathway, the distal common pathway is the ventricle, the retrograde pathway is the accessory pathway, and the proximal common pathway is the atrium (see Fig. 40-10). Additionally, this macroreentrant tachycardia could also be initiated by a premature ventricular impulse that first conducts retrograde over the accessory pathway, then antegrade through the AV nodal pathway. This sequence of events (down the AV node, up the accessory pathway), termed *orthodromic AVRT*, is the common variety of reentry in patients with an accessory AV pathway, resulting in a narrow QRS tachycardia (Fig. 40-6). In the uncommon variety, conduction proceeds in the opposite direction (down the accessory pathway, up the AV node), resulting in a wide QRS tachycardia, which is termed *antidromic AVRT*. Patients with WPW syndrome can have a third type of tachycardia, namely, AF. The occurrence of AF in the setting of an accessory AV pathway can be extremely serious. As AF is an extremely rapid atrial tachycardia, conduction can proceed down the accessory AV pathway, resulting in a very fast ventricular response or even VF and SCD. Unlike the AV nodal pathway, the refractory period of the accessory pathway shortens in response to rapid stimulation rates.

General Approach to Treatment

Both pharmacologic and nonpharmacologic methods have been used to treat patients with PSVT. Medications used in the treatment of these arrhythmias can be divided into three broad categories: (a) those that directly or indirectly increase vagal tone to the AV node (eg, digoxin); (b) those that depress conduction through slow, calcium-dependent tissue (eg, adenosine, β-blockers, and non-DHP CCBs); and (c) those that depress conduction through fast, sodium-dependent tissue (eg, quinidine, procainamide, disopyramide, and flecainide). Medications within these categories alter the electrophysiologic characteristics of the reentrant substrate so that PSVT cannot be sustained. In PSVT caused by AVNRT, class I AADs, such as flecainide, act primarily on the retrograde fast pathway. Digoxin and β-blockers may work on either the retrograde fast or the antegrade slow pathway. Verapamil, diltiazem, and adenosine prolong conduction time and increase refractoriness, primarily in the slow antegrade pathway of the reentrant loop. In PSVT caused by AVRT, class I AADs increase refractoriness in the fast accessory pathway or within the His-Purkinje system. β-Blockers, digoxin, adenosine, and verapamil all act by their effects on the AV nodal (antegrade, slow) portion of the reentrant circuit. Regardless of the mechanism, treatment measures are directed first at terminating an acute episode of PSVT and then at preventing symptomatic recurrences of the arrhythmia.

Acute management (Fig. 40-11) for patients with AVNRT or orthodromic AVRT include vagal maneuvers and/or adenosine.[53] Vagal techniques, such as unilateral carotid sinus massage, Valsalva maneuver, ice water facial immersion, or induced retching, are about 20% successful in terminating these PSVTs. Carotid massage and Valsalva maneuver are the simplest, least obtrusive, and most frequently used of these techniques. Should these techniques and/or adenosine be ineffective or unfeasible in a hemodynamically unstable patient (ie, syncope, pre-syncope, angina, or severe HF), synchronized DCCV is the next step. Even at low energy levels (such as 25 J), DCCV is almost always effective in quickly restoring SR and correcting symptomatic hypotension. If vagal techniques and/or adenosine are ineffective or unfeasible in patients who are hemodynamically stable, the next course of action would be administration of IV β-blockers or non-DHP CCBs (oral could be used with AVNRT). Approximately 80% to 98% of patients with a narrow QRS, regular arrhythmia (AVNRT or orthodromic AVRT) given adenosine (6 to 12 mg) will revert to SR within seconds; and, those given IV verapamil (5 to 10 mg), IV diltiazem (15 to 25 mg) will revert to SR within 5 minutes.[62] However, if AVNRT is unable to be corrected with these measures, IV amiodarone can be utilized.[53] For patients with AVRT, the next step would be synchronized cardioversion.

FIGURE 40-11

Algorithm for the treatment of acute (*top panel*) orthodromic AVRT/AVNRT and chronic prevention of recurrences (*bottom panel*). (AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; IV, intravenous; non-DHP CCBs, non-dihydropyridine calcium channel blockers.) *Note*: Medications are listed in alphabetical order, not in order of preference.

Should a patient have preexcited AF, synchronized cardioversion should be used if hemodynamically unstable.[53] If the patient is hemodynamically stable, IV ibutilide or procainamide can be administered. IV digoxin, IV amiodarone, oral or IV β-blockers, diltiazem, and verapamil should be avoided in patients with preexcited AF as they may increase conduction over the accessory pathway leading to an increase in the ventricular rate and enhance the risk of provoking a life-threatening ventricular arrhythmia.

Once the acute episode of AVNRT or AVRT is terminated, a decision on long-term preventive therapy must follow (Fig. 40-11). Preventive treatment is indicated if: (a) frequent episodes occur that necessitate therapeutic intervention (ie, emergency department visits) or cause symptoms that interfere with the patient's lifestyle; or (b) episodes are infrequent but cause severe symptoms. If preventive treatment is deemed necessary, either medication therapy or catheter ablation can be used.

AADs are no longer the treatment of choice to prevent recurrences of reentrant PSVT for the following reasons: (a) lifelong treatment is necessary in these generally young, but otherwise healthy, individuals; (b) there are few, if any, large controlled or comparative trials to assist the clinician in rationally choosing effective agents; and (c) most importantly, other nonpharmacologic treatments are clearly more effective. Nevertheless, medication therapy may occasionally be necessary in some patients, particularly those with mild symptoms and infrequent recurrences. A trial-and-error approach may be used, complemented by the use of ambulatory electrocardiographic recordings (Holter) or telephonic transmissions of cardiac rhythm (event monitors) to objectively document the efficacy or failure of the chosen medication regimen. Medications known to be effective in preventing recurrences of these arrhythmias are the AV nodal blocking medications (digoxin, β-blockers, non-DHP CCBs, and combinations of these agents) and the class Ic AADs (flecainide, propafenone).[53] Sotalol, dofetilide, and amiodarone can be considered alternatives. Although rarely used, digoxin is only indicated in orthodromic AVRT without preexcitation.

⑤ Catheter ablation using radiofrequency current on the PSVT substrate has dramatically altered the traditional treatment of these patients (Fig. 40-12). Radiofrequency ablation is highly effective, preventing the recurrences of PSVT in more than 90% of patients.[63,64] The procedure was originally used in patients with WPW syndrome.[63] In these patients, the extranodal pathway is most often located at the left lateral free wall between the left atrium and ventricle at the level of the mitral valve (see Fig. 40-12). During invasive electrophysiologic studies, portions of the reentrant circuit can be located (or mapped) using several catheters. Once this is completed, either radiofrequency or cryo ablation is performed, causing cell death in the tissue necessary for reentry. In this way, the substrate for reentry is destroyed, “curing” the patient of recurrent episodes of PSVT and obviating the need for chronic medication therapy. Thereafter, a similar approach was developed for patients with AVNRT, placing the catheter just anterior to the coronary sinus, below the His bundle and in the region of the slow pathway.[64] The preferred method in these individuals is to apply lesions to the slow pathway of the reentrant circuit in order to modify its properties enough so that AVNRT cannot recur. Complications, although unusual, include cardiac tamponade, pericarditis, valvular insufficiency, and AV block. Ablation of the extranodal connection occurs promptly, and evidence of preexcitation (delta waves) disappears.

Catheter ablation is the preferred treatment strategy (over AADs) for patients with symptomatic PSVT because the procedure is highly effective and curative, rarely results in complications, and obviates the need for chronic AAD therapy.[53]

Ventricular Arrhythmias

The common ventricular arrhythmias include (a) premature ventricular complexes (PVCs), (b) VT, and (c) VF. These arrhythmias may result in a wide variety of symptoms. PVCs often cause no symptoms or only mild palpitations. VT may be a life-threatening situation associated with hemodynamic collapse or may be totally asymptomatic. VF, by definition, is an acute medical emergency necessitating cardiopulmonary resuscitation (CPR).

Premature Ventricular Complexes and Sudden Cardiac Death

PVCs (Fig. 40-6) are very common ventricular rhythm disturbances that occur in patients with or without SHD. Experimental models show that PVCs may be elicited by abnormal automaticity, triggered activity, or reentrant mechanisms. PVCs are commonly observed in healthy individuals; in these patients, the PVCs seem to have little, if any, prognostic significance. PVCs occur more frequently and in more complex forms in patients with SHD than in healthy individuals. The prognostic meaning of PVCs has been well studied in patients with MI (acute or remote) with several consistent themes. Patients with some forms of PVCs (ie, multifocal or couplets) are at higher risk for SCD, defined as unexpected death (without an obvious noncardiac cause) occurring in a patient within 1 hour of experiencing symptoms (witnessed episodes) or within 24 hours of last being observed in normal health (unwitnessed episodes).[65] Studies of patients who experienced SCD (and happened to be wearing an electrocardiographic monitor at the time) often demonstrate the cause to be VF preceded by a short run of VT and frequent PVCs.[66]

General Approach to Treatment

Historically, investigators promoted the concept that patients in the acute phase of MI may have types of PVCs that are predictive of VF and SCD. These types of PVCs were referred to as “warning arrhythmias” and included frequent ventricular ectopy (more than 5 beats/min), multiform configuration (different morphology), couplets (two in a row), and R-on-T phenomenon (PVCs occurring during the repolarization phase of the preceding sinus beat in the vulnerable period of ventricular recovery). However, as a result of using continuous electrocardiographic monitoring techniques, it is apparent that almost all patients have warning arrhythmias in the acute MI setting. In those patients who experience VF, warning arrhythmias are no more common than in those without VF. Consequently, warning arrhythmias observed during acute MI are neither sensitive nor specific for determining which patients will have VF. Thus, there is little need to direct medication therapy specifically at PVC suppression in these patients. Studies show that effective prevention of VF in the acute MI setting may be achieved without the abolition of PVCs.

Conversely, data strongly imply that PVCs documented in the convalescence period of MI do carry important long-term prognostic significance.[67] PVCs occurring after an MI seem to be a risk factor for patient death that is independent of the degree of LV dysfunction or the extent of coronary atherosclerosis. Using a classification of PVCs (simple or benign [infrequent and monomorphic] versus complex [at least 5 PVCs/min, couplets, R-on-T beats, and multiform]), investigators found that complex (but not simple) ventricular ectopy in the setting of CAD was associated with a higher incidence of overall mortality and cardiac death.[67]

PVCs carry little or no risk when the frequency is low and individuals are without SHD; thus, medication therapy is unnecessary. However, because of the prognostic significance of complex PVCs in patients with SHD, the use of AAD therapy to suppress them has been controversial. Historically, many supported the aggressive use of AAD therapy to suppress PVCs, based on the underlying premise of eliminating a risk factor for SCD in patients with CAD (namely, the presence of complex PVCs). However, others favored a more conservative approach and disregarded the use of AAD therapy in the absence of significant symptoms. An important study, the Cardiac Arrhythmia Suppression Trial (CAST), abruptly put an end to this debate in noteworthy fashion. This trial was conducted to determine if suppression of ventricular ectopy with encainide, flecainide, or moricizine could decrease the incidence of death from arrhythmia in patients who had suffered an MI.[68] In the trial, patients with an LVEF less than or equal to 55% (0.55) (if recruited within 90 days of the MI) or an LVEF less than or equal to 40% (0.40) (if recruited at least 90 days after the MI) were randomized to receive encainide, flecainide, moricizine, or placebo. Compared with placebo, treatment with encainide or flecainide was associated with a significantly higher rate of total mortality and death due to arrhythmia, presumably caused by proarrhythmia. Analysis of the moricizine arm indicated neither harm nor benefit from this therapy; therefore, only this portion of the study was allowed to continue as CAST II.[69] However, CAST II was also prematurely discontinued because there was a trend toward an increase in mortality in moricizine-treated patients. Moreover, quinidine and sotalol have also been shown to increase the risk of death in patients with a HFrEF and PVCs.[70]

Currently, only two AADs have been shown *not* to increase mortality in post-MI patients with long-term use: amiodarone and dofetilide. A number of trials have shown amiodarone to decrease the incidence of sudden (or arrhythmic) death, but not total mortality, in post-MI patients with complex ventricular ectopy.[71,72] Clearly, because of its impressive side effect profile and its inability to improve survival, amiodarone should not routinely be recommended in patients with heart disease such as remote MI and complex PVCs. Two randomized controlled trials have also shown that chronic therapy with dofetilide has no effect on overall mortality in post-MI patients with LV dysfunction.[73,74]

These results have clearly had a negative influence on the long-term use of all AADs, causing a broad skepticism in the risk-versus-benefit analysis of these medications. Consequently, pharmaceutical companies have shifted their medication discovery and investigative efforts away from potent sodium channel blockers. The findings of the CAST have also provided additional fuel for the pursuit of nonpharmacologic therapies for arrhythmias, such as catheter ablation and implantable devices.

⑦ How should the clinician approach the patient with documented asymptomatic PVCs? Clearly, attempts to suppress asymptomatic PVCs should *not* be made with any AAD. Indeed, those patients who are at risk for arrhythmic death (recent MI, LV dysfunction, complex PVCs) should also *not* be routinely given *any* class I or III AAD.[70] In post-MI patients, the use of β-blockers is associated with a reduction in mortality and SCD, especially in the presence of LV dysfunction. β-Blockers and non-DHP CCBs can be used in patients without underlying SHD to suppress symptomatic PVCs. If neither is effective in reducing recurrence and symptoms, class Ic AADs, amiodarone, or sotalol can be used. Uncommonly, patients have such frequent PVCs that are either extremely bothersome or result in the development of cardiomyopathy leading to a decline in left ventricular function (usually when the PVCS greater than 20% of all beats).[70] In these patients, ablation of the PVCs can be pursued.

Ventricular Tachycardia

VT is a wide QRS tachycardia (Fig. 40-6) that may acutely occur because of metabolic abnormalities, ischemia, or medication toxicity, or chronically recur as a paroxysmal form. On the ECG, VT may appear as repetitive monomorphic or polymorphic ventricular complexes. The definition of VT is three or more consecutive PVCs occurring at a rate of greater than 100 beats/min. An acute episode of VT may be precipitated by severe electrolyte abnormalities (hypokalemia or hypomagnesemia), hypoxia, or digoxin toxicity, or (most commonly) may occur in patients presenting with acute MI or myocardial ischemia complicated by HF. In these cases, correction of the underlying precipitating factors will usually prevent further recurrences of VT. As an example, if VT occurs during the first 24 hours of an acute MI, it will probably not reappear on a chronic basis after the infarcted area has been reperfused or healed with scar formation. This form of acute VT may be caused by a transient reentrant mechanism within temporarily ischemic or dying ventricular tissue. In contrast, some patients have a chronic, recurrent form of VT that is almost always associated with some type of underlying SHD. Common examples are paroxysmal VT associated with idiopathic dilated cardiomyopathy or remote MI with an LV aneurysm. In chronic, recurrent VT, microreentry within the distal Purkinje network and myocardium is responsible for the underlying substrate in a large majority of patients (see Fig. 40-13). Theoretically, electrophysiologic abnormalities occur as a result of structural damage and heart disease within the ventricular conducting system. The reentrant circuit may possess both anatomically determined and functional properties coursing through normal tissue, damaged (but not dead) tissue, and islands of necrosed tissue. In a minority of patients, macroreentrant circuits may be responsible for recurrent VT, including reentry incorporating the bundle branches. Patients with acute VT associated with a precipitating factor often suffer severe symptoms, requiring immediate treatment measures. Chronic, recurrent VT may also cause severe hemodynamic compromise but may also be associated with only mild symptoms that are generally well tolerated. The severity of symptoms is reliant upon the rate of the tachycardia and the patient's underlying heart disease and ventricular function.

FIGURE 40-13

Conduction system of the heart. The magnified portion shows a bifurcation of a Purkinje fiber traditionally explained as the etiology of reentrant VT. A premature impulse travels to the fiber which is damaged by heart disease or ischemia. It encounters a zone of prolonged refractoriness (area of unidirectional block; *cross-hatched area*) but fails to propagate because the fiber remains refractory to stimulation from the previous impulse. However, the impulse may slowly travel (*squiggly line*) through the other portion of the Purkinje twig and will "reenter" the cross-hatched area if the refractory period is concluded and the fiber is now excitable. Thus, the premature impulse never meets refractory tissue; circus movement ensues. If this site stimulates the surrounding ventricle repetitively, clinical reentrant VT results. (VT, ventricular tachycardia.)

Sustained VT is that which requires therapeutic intervention to restore a stable rhythm or persists for a relatively long time (usually more than 30 seconds). Nonsustained VT is that which self-terminates after a brief duration (usually less than 30 seconds). Patients who experience VT more frequently than SR (ie, VT is the dominant rhythm) are considered to have incessant VT. In monomorphic VT, the QRS complexes are similar in morphologic characteristics from beat to beat. In polymorphic VT, the QRS complexes vary in shape and/or size between beats. A characteristic type of polymorphic VT, in which the QRS complexes appear to undulate around a central axis and that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves), is referred to as TdP.

Most, but not all forms of recurrent VT occur in patients with extensive SHD. VT occurring in a patient without SHD is sometimes referred to as idiopathic VT and may take several forms including fascicular VT and ventricular outflow tract VT.[75-77] Fascicular VT arises from a fascicle of the left bundle branch (usually posterior) and is usually not associated with severe underlying SHD. Non-DHP CCBs are effective in terminating an acute episode of fascicular VT. Ventricular outflow tract VT (usually originating from the right ventricular outflow tract) originates from near the pulmonic valve (or uncommonly the aortic valve or LV outflow tract) and also occurs in patients with normal LV function without discernible SHD.[77] Unlike other forms of VT, right ventricular outflow tract VT often terminates with adenosine and may be prevented with β-blockers and/or non-DHP CCBs.

Some unusual forms of VT are congenital or heritable. TdP can be associated with heritable defects in the flux of ions that govern ventricular repolarization. Although multiple syndromes and genetic mutations have been described, the more common examples are long QT syndrome 1 (depressed I_{Ks}), long QT syndrome 2 (depressed I_{Kr}), and long QT syndrome 3 (enhanced, inward sodium ion flux during repolarization).[78] Polymorphic VT (without a prolonged QT interval) or VF may also occur due to a heritable defect in the sodium channel. This is the case in Brugada syndrome, which is described as a typical ECG pattern (ST-segment elevation in leads V_1 to V_3) in SR that is associated with SCD, and commonly occurs in young males.[70]

General Approach to Treatment

Consider the patient with the more common form of sustained monomorphic VT (ie, those with SHD, usually ischemic in nature). Like other rapid tachycardias, the initial management of an acute episode of VT (with a pulse) requires a quick assessment of the patient's signs and symptoms. An investigation should be made into possible precipitating factors which should be corrected if possible. The diagnosis of acute MI should always be entertained. If the episode of VT is thought to be an isolated electrical event associated with a transient initiating factor (such as acute myocardial ischemia or digoxin toxicity), there is no need for long-term AAD therapy once the precipitating factors are corrected (eg, an MI has been reperfused and healed and the patient is stable). Nevertheless, the patient should be monitored closely for possible recurrences of VT.

Patients presenting with an acute episode of sustained monomorphic VT and hemodynamically instability should have advanced cardiovascular life support (ACLS) initiated immediately, including DCCV to restore SR.[79] In patients with stable monomorphic VT treatment is driven by the presence of SHD. If a patient has SHD, cardioversion should be implemented and IV procainamide, amiodarone, or sotalol can be considered. For patients without SHD, verapamil and β-blockers are first-line options. See Fig. 40-14 for an algorithm to acutely manage monomorphic VT.

Once an acute episode of sustained VT has been successfully terminated by electrical or pharmacologic means and an acute MI has been ruled out, the possibility of a patient having recurrent episodes of VT should be considered. Evidence for the possibility of VT recurrence can often be gleaned from invasive electrophysiologic studies using programmed ventricular stimulation. Patients who survive an acute episode of sustained VT are at extremely high risk for death and the yield for finding an effective AAD via electrophysiologic testing is low. Amiodarone is the most effective (approximately 50% effective after 2 years) AAD in patients with recurrent VT. However, nonpharmacologic approaches have demonstrated impressive effectiveness in the treatment of recurrent VT/VF.[70] For instance, some forms of recurrent VT are amenable to catheter ablation therapy using radiofrequency current. This approach is highly effective (approximately 90%) in idiopathic VT (right ventricular outflow tract or fascicular VT), but less so in recurrent VT associated with a cardiomyopathic process or remote MI with LV aneurysm. In the latter patients, ablation is usually regarded as second-line therapy after other methods have failed.[80] Numerous trials have established ICDs as a superior treatment over AADs not only for the prevention of SCD in patients who have been resuscitated from an episode of cardiac arrest or had sustained VT ("secondary prevention") but also for the prevention of an initial episode of SCD in certain high-risk patient populations (“primary prevention”).

Implantable Cardioverter-Defibrillator

8 The introduction of and advances in the ICD (Fig. 40-15) have obviated the need for AADs to prevent episodes of life-threatening ventricular arrhythmias.[70,81] Numerous advancements in device technology have allowed the ICD to become smaller, less invasive to implant, and programmable with advanced functions. Early ICDs required a thoracotomy to place the generator in the abdomen, whereas with the newer, smaller models, the leads are implanted transvenously with the generator placed into the pectoral region in a manner similar to cardiac pacemakers. Modern ICDs now employ a “tiered-therapy approach,” meaning that overdrive or antitachycardia pacing (stimulates the heart to go faster than the rate induced by the VT) can be attempted first to terminate the tachyarrhythmia (no shock delivered), followed by low-energy cardioversion, and, finally, by high-energy defibrillation shocks. In addition, backup antibradycardia pacing and extended battery lives have made these newer devices much more attractive. All models store recordings during delivery of pacing shocks, which is extremely important in discerning appropriate shocks (ie, delivers shock for serious ventricular arrhythmia) from inappropriate shocks (ie, delivers shock for AF with rapid ventricular rate) and in documenting true recurrences of the patient’s tachycardia.

Although ICDs are highly effective for preventing SCD due to recurrent VT or VF, several problems remain. First, the device itself, the implantation procedure, electrophysiologic studies, hospitalization, and physician fees are costly. Second, many patients with ICDs end up receiving concomitant AAD therapy (usually amiodarone or sotalol).[81,83] AADs can be initiated in these patients for a number of reasons, including: (a) decreasing the frequency of VT/VF episodes to subsequently reduce the frequency of appropriate shocks; (b) reducing the rate of VT so that it can be terminated with anti-tachycardia pacing; and (c) decreasing episodes of concomitant supraventricular arrhythmias (eg, AF, AFl) that may trigger inappropriate shocks. As a result of these potential benefits, the concomitant use of AADs can minimize patient discomfort and prolong the battery life of the ICD. The decision to initiate concomitant AAD therapy should be individualized, with treatment usually being reserved for those patients with frequent shocks because of VT or AF.

Prevention of Sudden Cardiac Death

First-line therapy for the secondary prevention of SCD is ICD implantation as the rate of survival is superior to that of AADs in patients who are at high risk for recurrent, life-threatening ventricular arrhythmias.[84-86] Patient populations at high risk for a first episode of SCD include those with a prior MI, HFrEF, and nonsustained VT. The use of AADs to prevent SCD in this high-risk group has been significantly limited by the results of the CAST and similar trials that have collectively demonstrated that these medications may increase mortality in these patients. As a result of these trials, clinicians have sought a more clearly defined strategy for risk stratification in these patients before initiating medication therapy.

⑨ For patients with nonsustained VT, there are four treatment strategies based upon symptoms and underlying comorbidities: (a) conservative (ie, no AAD treatment beyond β-blockers); (b) empiric amiodarone or sotalol; (c) ablation; and (d) aggressive (ie, electrophysiologic studies with possible insertion of an ICD) (Fig. 40-16).[70] A number of early studies suggested that tests such as electrophysiologic studies could be used to determine long-term risk in patients with nonsustained VT.[87,88] For instance, one study demonstrated that post-MI patients with nonsustained VT and inducible sustained VT after programmed stimulation were at increased risk for subsequent VT/VF or SCD compared with those in whom sustained VT could not be induced.[87] These data led to the evaluation of the efficacy of ICD therapy in this high-risk patient population.[89,90] The first trial to test this hypothesis randomized patients with a previous MI, HFrEF, asymptomatic nonsustained VT, and inducible VT that was not suppressed with the use of IV procainamide to receive an ICD or conventional medical therapy (74% received amiodarone).[89] This trial was terminated prematurely after a significant survival benefit was detected in the ICD group. A subsequent study randomized patients with a history of MI, HFrEF, and either asymptomatic nonsustained VT or inducible sustained VT to treatment using a conservative approach (no AAD therapy beyond β-blockers) or electrophysiologically guided therapy (AADs and/or ICD).[90] The conservative approach had a significantly higher event rate (cardiac arrest or death from arrhythmia). Furthermore, patients in the electrophysiologically guided group receiving only AADs (no ICD) had similar event rates to the conservative therapy group. In other words, only those treated with an ICD had a significantly lower event rate and greater survival. Based on the results of these trials, it is reasonable for patients with CAD, HFrEF, and nonsustained VT to undergo electrophysiologic testing.[70] If these patients do have inducible sustained VT/VF, implantation of an ICD is warranted.

FIGURE 40-16

Algorithm for the primary prevention of SCD in patients with a history of MI or with a nonischemic dilated cardiomyopathy. LVEF of 35% is equivalent to 0.35 expressed as a fraction. (a) In these patients, the β-blocker is being used to reduce post-MI mortality. (b) Patients should be >40 days post-MI and at least 90 days postrevascularization prior to insertion of the ICD. The effectiveness of ICDs in patients with nonsustained VT led to the study of their benefit in patients at high risk for but no prior history of ventricular arrhythmias. In a study of patients with a prior MI and HFrEF (prior history of ventricular arrhythmia or electrophysiologic testing not required), those treated with an ICD experienced a significant reduction in mortality compared with the conventional therapy group (routine post-MI and HF therapy).[91] The reduction in the ICD group was primarily due to a reduction in arrhythmic death. A similar study randomized patients with NYHA class II or III HFrEF (of either ischemic or nonischemic etiology) to receive placebo, amiodarone, or an ICD in addition to standard HF therapies.[92] Implantation of an ICD resulted in a significantly lower mortality rate compared with both placebo and amiodarone (there was no difference between placebo and amiodarone). The survival benefits of the ICD were observed regardless of the etiology of the HF.

⑨ Overall, as the ICD trials have evolved over the past decade, the indications for implanting these devices have significantly expanded, and many patients are eligible for an ICD.[70,93]

Ventricular Proarrhythmia

All AADs have the potential to aggravate existing arrhythmias or to cause new arrhythmias. AADs may cause proarrhythmia in nearly 30% of patients.[94] Many definitions for proarrhythmia have been proposed; however, in the simplest terms, it indicates the development of a significant new arrhythmia (such as VT, VF, or TdP) or worsening of an existing arrhythmia (episodes are longer, faster, or more frequent). As with all arrhythmias, the consequences of proarrhythmia are varied. Some patients who develop proarrhythmia may be totally asymptomatic, others may notice a worsening of symptoms, and some may die suddenly. The development of proarrhythmia results from the same mechanisms that cause arrhythmias in general (eg, quinidine-induced TdP due to EADs) or from an alteration in the underlying substrate due to the AAD (eg, development of an accelerated tachycardia caused by flecainide, which decreases conduction velocity without significantly altering the refractory period).[67] The diagnosis of proarrhythmia is sometimes difficult to make because of the variable nature of the underlying arrhythmias. However, in all cases, the AAD should be discontinued if proarrhythmia is detected or suspected.

Monomorphic Ventricular Tachycardia

⑩ The prototypical form of proarrhythmia caused by the class Ic AADs is a rapid, sustained, monomorphic VT with a characteristic sinusoidal QRS pattern that is often resistant to resuscitation with cardioversion or overdrive pacing. It is sometimes referred to as sinusoidal or incessant VT and is the result of excessive sodium channel blockade and slowed conduction. Sinusoidal VT caused by the class Ic AADs was thought to occur within the first several days of medication initiation. However, the results of the CAST indicate that the risk for this type of proarrhythmia may exist as long as the AAD is continued. Factors that can predispose a patient to this form of proarrhythmia include: (a) the presence of underlying ventricular arrhythmias; (b) CAD; and (c) LV dysfunction. Provocation of proarrhythmia by the class Ic AADs is sometimes reported during exercise, which is most likely a result of augmented slowed conduction at rapid heart rates (ie, rate-dependent sodium blockade). The incidence of proarrhythmia caused by class Ic AADs is greatest in patients with all three of the above risk factors (approximately 10%-20%) and extremely uncommon in those without these risk factors, such as patients with supraventricular tachycardias and normal LV function. Other factors that have a less well-defined association with proarrhythmia are elevated AAD serum concentrations and rapid dosage escalation of the AAD. The presence of underlying ventricular conduction delays may also pose a risk for proarrhythmia. As mentioned earlier, incessant monomorphic VT is often resistant to resuscitation. However, some have had success with lidocaine (“fast on–off” AAD, which successfully competes with a “slow on–off” agent such as flecainide for sodium channel receptor) or sodium bicarbonate (reverses the excessive sodium channel blockade).

Torsades de Pointes

⑩ TdP is a rapid form of polymorphic VT (Fig. 40-6) that is associated with evidence of delayed ventricular repolarization (long QT interval) on ECG. Most forms of polymorphic VT occurring in the setting of a normal QT interval are similar to monomorphic VT in terms of etiology and treatment strategies (thus, a long QT interval is crucial to the diagnosis of TdP). Much has been learned about the underlying etiology of TdP. Basic defects (genetic, medications, or diseases) that delay repolarization by influencing ion movement (usually by blocking potassium efflux) provoke EADs preferentially in cells deep in the heart muscle, which, in turn, trigger reentry and TdP. Drugs that cause TdP usually delay ventricular repolarization in an inhomogeneous way (termed *dispersion of refractoriness*), which facilitates the formation of multiple reentrant loops in the ventricle.[95] TdP may occur in association with hereditary syndromes or as an acquired form (ie, a result of medications or diseases). The underlying etiology in both cases is delayed ventricular repolarization due to blockade of potassium conductance. It is possible, however, that some individuals have a partially expressed form of these congenital syndromes but never suffer TdP unless some other external factor (eg, medications, diseases, electrolyte disturbances, abrupt heart rate changes) further delays ventricular repolarization. Specifically, acquired forms of TdP are associated with electrolyte disturbances (hypokalemia or hypomagnesemia), subarachnoid hemorrhage, myocarditis, liquid protein diets, arsenic poisoning, severe hypothyroidism, or, most commonly, medication therapy (notably phenothiazines, antibiotics, antihistamines, antidepressants, and AADs) (Table 40-13).

TABLE 40-13

Potential Causes of QT Interval Prolongation and Torsades de Pointes

Conditions

Congenital long QT syndromes

Heart failure

Hypokalemia

Hypomagnesemia

Myocardial ischemia/infarction

Myocarditis

Severe bradycardia (<50 beats/min)

Severe hypothermia

Severe starvation/liquid protein diets

Subarachnoid hemorrhage

Medications

Antiarrhythmic medications

- Amiodarone (<1%)
- Disopyramide
- Dofetilide
- Dronedarone
- Ibutilide
- Procainamide
- Quinidine
- Sotalol

Antiinfectives

- Azole antifungals (eg, fluconazole, voriconazole)
- Fluoroquinolones (eg, levofloxacin, moxifloxacin, gemifloxacin)
- Macrolides
- Pentamidine
- Chloroquine

Cancer chemotherapy or biologic agents

- Oxaliplatin
- Vandetanib

Methadone

Ondansetron (IV)

Psychotropics

- Citalopram
- Escitalopram
- Droperidol
- Haloperidol
- Phenothiazines (eg, thioridazine, chlorpromazine)
- Pimozide

Toxins

- Arsenic
- Organophosphate insecticides

IV, intravenous

Note: For a complete list, see www.crediblemeds.org.

The class Ia AADs (especially quinidine) and class III I_{Kr} blockers are most notorious for precipitating TdP; the class Ib and Ic AADs rarely, if ever, cause TdP as they do not appreciably delay repolarization. Most AADs with I_{Kr} blocking activity cause TdP in approximately 2% to 4% of patients, with the exceptions being amiodarone and dronedarone (less than 1%). Risk factors and associated features of medication-induced TdP have been identified and summarized in Table 40-14.[96] However, none of these associations are absolute prerequisites to the development of medication-induced TdP. For instance, although TdP is usually documented early in the course of quinidine therapy, patients may develop this arrhythmia anytime during chronic treatment.[97] The reason for quinidine's unique propensity for causing TdP at relatively low dosages and plasma concentrations requires explanation. Quinidine's ability to block I_{Kr} is clinically manifest at low plasma concentrations; at higher plasma concentrations, its sodium channel blocking properties predominate. Other medications that block I_{Kr} usually do so in a concentration-dependent fashion. The observation that most patients who suffer medication-induced TdP have evidence of mildly delayed repolarization (long QT intervals) even before they are prescribed the offending medication has stimulated a search for a potential genetically linked risk. Indeed, it appears that at least some patients with acquired medication-induced TdP possess mutations of genes that encode for I_{Kr} or I_{Ks}.[96]

TABLE 40-14

Risk Factors Associated with Drug-Induced Torsades de Pointes

High dosages or plasma concentrations of the offending medication
Concurrent SHD (eg, CAD, HF, and/or LV hypertrophy)
Prolonged QT interval at baseline
Prolonged QT interval shortly after initiation of the offending medication
Concomitant electrolyte disturbances (ie, hypokalemia or hypomagnesemia)
Female gender
A characteristic long-short initiating sequence of the TdP episode ()
Bradycardia
Concomitant QT interval prolonging medications

CAD, coronary artery disease; HF, heart failure; LV, left ventricular; SHD, structural heart disease; TdP, torsades de pointes.

The common underlying electrophysiologic cause of TdP is a delay in ventricular repolarization (provoking EADs), which usually results from inhibition (medication-induced or genetic) of the I_K current and manifests as QT interval prolongation on the ECG. Therefore, the extent of QT interval prolongation has been used as a measurement of risk of TdP. However, considerable controversy exists regarding this practice. Amiodarone, for example, commonly causes significant QT prolongation but is a relatively infrequent cause of TdP. Nonetheless, the QT interval should be measured and monitored in all patients prescribed medications that have a high potential for causing TdP (see Table 40-3). Patients with a prolonged QT_c interval at baseline (QT interval corrected for heart rate, which can be calculated using Bazett's formula: $QT_c = QTmeasured/\sqrt{R - RInterval}$ QTc=QTmeasured/R−RInterval) (ie, greater than 450 msec in men; greater than 470 msec in women) should not be given medications that have a high potential for causing TdP. The development of clinically significant QTc interval prolongation (ie, QTc interval greater than 500 msec or an increase in the QTc interval of more than 60 to 70 msec from baseline) after initiation of a medication is an indication to discontinue the agent or, at least, to reduce its dosage and carefully monitor.[98]

Drug-induced TdP has become an extremely visible hazard plaguing new medications, sometimes resulting in public health disasters. For instance, several medications (cisapride, astemizole, levomethadyl, grepafloxacin, sparfloxacin, terfenadine, and high-dose [32 mg] IV ondansetron) have been withdrawn from the market in the United States because of their significant potential for causing TdP. Thus, all new medication entities under investigation are screened for their ability to block I_K and cause significant QT prolongation.

Acute treatment of TdP is different than treatment for the more common acute monomorphic VT. For an acute episode of TdP, most patients will require and respond to defibrillation. However, TdP tends to be paroxysmal in nature and often will rapidly recur after defibrillation. Therefore, after the initial restoration of a stable rhythm, therapy designed to prevent recurrences of TdP should be instituted. AADs that further prolong repolarization, such as IV procainamide, are absolutely contraindicated. Lidocaine is usually ineffective. Although there are no true efficacy trials, IV magnesium sulfate, by suppressing EADs, is considered the medication of choice in preventing recurrences of TdP.[70] If IV magnesium sulfate is ineffective, treatment strategies designed to increase heart rate, shorten ventricular repolarization, and prevent the pause dependency should be initiated. Either temporary transvenous pacing (105-120 beats/min) or pharmacologic pacing (isoproterenol) can be initiated for this purpose. All medications that prolong the QT interval should be discontinued, and exacerbating factors (eg, hypokalemia or hypomagnesemia) should be corrected.

Ventricular Fibrillation

VF (Fig. 40-6) is electrical anarchy of the ventricle resulting in no cardiac output and CV collapse. Death will ensue rapidly if effective treatment measures are not taken. Patients who die abruptly (within 1 hour of initial symptoms) and unexpectedly (ie, “sudden death”) usually have VF recorded at the time of death.[99] SCD accounts for more than 360,000 deaths per year in the United States.[13] It occurs most commonly in patients with CAD or LV dysfunction, but occasionally in those without associated heart disease (eg, Brugada syndrome). When a patient experiences sudden cessation of cardiac activity with no normal breath or signs of circulation, they are said to have sudden cardiac arrest. CPR, medications, and defibrillation can be corrective measures to prevent SCD. If the event is not associated with acute MI, sustained VT and/or VF during electrophysiologic studies are often inducible. These individuals are at high risk for the recurrence of VT and/or VF. In contrast, patients who have VF associated with acute MI (ie, within 48 hours of hospital presentation) usually have little risk of recurrence.

In the presence of acute coronary syndrome, CAD should be treated. The patient’s LVEF should be reevaluated 40 days post-MI and 90 days postrevascularization.[70] If the LVEF is greater than 35% (0.35), the patient should be treated with medical management; however, if the LVEF is less than 35% (0.35), an ICD should be considered. Without acute coronary syndrome, the patient should be evaluated for SHD and inherited arrhythmia syndrome. Regardless, reversible causes should be eliminated (ie, discontinue the offending medication or correct electrolytes) and avoided. If no reversible cause is identified, an ICD can be considered.

Acute Management

A patient with pulseless VT or VF should have advanced cardiovascular life support (ACLS) initiated immediately, including defibrillation to restore SR.[100] A detailed discussion regarding the acute management of pulseless VT/VF can be found in Chapter 41, “Cardiopulmonary Arrest.”

Bradyarrhythmias

For the most part, the symptoms of bradyarrhythmias result from a decline in cardiac output. Because cardiac output decreases as heart rate decreases (to a point), patients with bradyarrhythmias may experience symptoms in association with hypotension, such as dizziness, syncope, fatigue, and confusion. If LV dysfunction exists, patients may experience worsening HF symptoms. Except in the case of recurrent syncope, symptoms associated with bradyarrhythmias are often subtle and nonspecific.

Sinus Bradycardia

Sinus bradyarrhythmias (heart rate less than 60 beats/min) are a common finding, especially in young, athletically active individuals, and usually are neither symptomatic nor in need of therapeutic intervention. On the other hand, some patients, particularly the elderly, have SND. This may be the result of underlying SHD and the normal aging process that attenuate SA nodal function over time resulting in symptomatic sinus bradycardia and/or periods of sinus arrest.[93] SND is usually reflective of diffuse conduction disease and accompanying AV block is relatively common. Furthermore, symptomatic bradyarrhythmias may be accompanied by alternating periods of paroxysmal tachycardias such as AF. In this instance, AF sometimes presents with a rather slow ventricular response (in the absence of AV nodal blocking medications) because of diffuse conduction disease. The occurrence of alternating bradyarrhythmias and tachyarrhythmias is referred to as the tachy-brady syndrome. The occurrence of paroxysmal AF in a patient with SND may be a result of underlying SHD with atrial dysfunction or atrial escape in response to reduced sinus node automaticity. In fact, because the rate of impulse generation by the sinus node is generally depressed or may fail altogether, other automatic pacemakers within the conduction system may "rescue" the sinus node. These rescue rhythms often present as paroxysmal atrial rhythms (eg, AF) or as a junctional escape rhythm.

The treatment of SND involves eliminating the symptomatic bradycardia and potentially managing alternating tachycardias such as AF. In general, the long-term therapy of choice is permanent pacemaker implantation.[81,93] Pacing clearly improves symptoms and overall quality of life and decreases the incidence of paroxysmal AF and systemic embolism. Drugs commonly employed to treat supraventricular tachycardias should be used with caution, if at all, in the absence of a functioning pacemaker. AADs prescribed to prevent AF recurrences may also suppress the escape or rescue rhythms that appear in severe sinus bradycardia or sinus arrest. Consequently, these medications may transform an asymptomatic patient with bradycardia into a symptomatic one. Other medications that depress SA or AV nodal function, such as β-blockers, non-DHP CCBs, and ivabradine, may also significantly exacerbate bradycardia. Drugs with indirect sympatholytic actions, such as methyldopa and clonidine, may also worsen SND. The use of digoxin in these patients is controversial; however, in most cases, it can be used safely.

Another reason for paroxysmal bradycardia and sinus arrest, not directly due to SND, is carotid sinus syndrome.[101,102] This syndrome occurs commonly in the elderly with underlying SHD and may precipitate falls and hip fractures. Symptoms occur when the carotid sinus is stimulated, resulting in an accentuated baroreceptor reflex. Often, however, symptoms are not well correlated with the obvious physical manipulation of the carotid sinus (in the lateral neck region). Patients may experience intermittent episodes of dizziness or syncope because of sinus arrest caused by increased vagal tone (the cardioinhibitory type), a drop in systemic blood pressure caused by sympathetic withdrawal (the vasodepressor type), or both (mixed cardioinhibitory and vasodepressor types). The diagnosis can be confirmed by performing carotid sinus massage with ECG and blood pressure monitoring in a controlled setting. Symptomatic carotid sinus hypersensitivity should be treated with permanent pacemaker therapy.[93] However, some patients, particularly those with a significant vasodepressor component, still experience syncope or dizziness even after pacemaker implantation.

Vasovagal syndrome, by causing bradycardia, sinus arrest, and/or hypotension, is the cause of syncope in many patients who present with recurrent fainting of unknown origin.[102] Many individuals can recount rare instances of fainting spells at times of duress or fear while others may have extremely frequent, unexpected syncopal episodes that interfere with the patient's quality of life and cause physical danger (sometimes referred to as neurocardiogenic syncope syndrome or malignant vasovagal syndrome). Although the true mechanism is uncertain, vasovagal syncope is presumed to be a neurally mediated, paradoxical reaction involving stimulation of cardiac mechanoreceptors, forceful contraction of the ventricle (eg, as with adrenergic stimulation), and low ventricular volumes (eg, with upright posture or dehydration) leading to transient hypotension (sympathetic withdrawal), bradycardia (vagotonia), and syncope. Patients believed to have frequent episodes of vasovagal syncope may undergo an upright body-tilt test to establish the diagnosis, although the value of this test has been questioned.[102]

Patients with vasovagal syncope should receive education targeting awareness and trigger avoidance (ie, prolonged standing or warm environments).[102] First-line treatment includes counter-pressure maneuvers (ie, laying on the ground, squatting, etc.), followed by increasing salt and fluid intake, when not contraindicated. The drug of choice is midodrine, which has been associated with a 43% reduction in syncope recurrence. Midodrine is an alpha-agonist that reduces the peripheral sympathetic neural outflow that causes venous pooling and vasodepression. Although it may seem inappropriate to treat a syndrome resulting from vasodilation and bradycardia with a medication that slows heart rate and reduces blood pressure, β-blockers are used to prevent episodes of vasovagal syncope in patients 42 years of age and older. The rationale for their use is that they inhibit the sympathetic surge that causes forceful ventricular contraction and precedes the onset of hypotension and bradycardia. Other medications that have been used successfully include mineralocorticoids as volume expanders (fludrocortisone) and selective serotonin receptor antagonists (sertraline, paroxetine). Dual-chamber pacemakers can be used but should be reserved for at least 40 years of age with recurrent episodes and prolonged spontaneous pauses.

Atrioventricular Block

Conduction delay or block may occur in any area of the AV conduction system: the AV node, the His bundle, or the bundle branches. AV block is usually categorized into three different types based on ECG findings (Table 40-15). First-degree AV block is 1:1 AV conduction with a prolonged PR interval.

Second-degree AV block is divided into two forms: Mobitz I AV block (Wenckebach periodicity) is less than 1:1 AV conduction with progressively lengthening PR intervals until a ventricular complex is dropped; Mobitz II AV block is intermittently dropped ventricular beats in a random fashion without progressive PR lengthening. Third-degree AV block is complete heart block where AV conduction is totally absent (AV dissociation). First-degree AV block usually represents prolonged conduction in the AV node. Mobitz I, second-degree AV block is also usually caused by prolonged conduction in the AV node. In contrast, Mobitz II, second-degree AV block is usually caused by conduction disease below the AV node (ie, His bundle). Third-degree AV block may be caused by disease at any level of the AV conduction system: complete AV nodal block, His bundle block, or trifascicular block. In this situation, the ventricle beats independently of the atria (AV dissociation), and the rate of ventricular activation and QRS configuration are determined by the site of the AV block. The usual degree of automaticity of ventricular pacemakers progressively declines as the site of impulse generation moves down the ventricular conduction system. Therefore, the ventricular escape rate in cases of trifascicular block will be significantly less than complete AV nodal block. Consequently, trifascicular block is a much more dangerous form of AV block. For instance, complete AV block at the level of the AV node usually results in the ventricular rhythm being controlled by the stable AV junctional pacemaker (rate approximately 40 beats/min). In contrast, in complete AV block due to trifascicular or His bundle block, a much less reliable pacemaker with slower rates below the site of block controls ventricular rhythm.

TABLE 40-15

Forms of Atrioventricular Block

Type	Criteria	Site of Block
First-degree block	Prolonged PR interval (>0.2 second)	Usually AVN
	1:1 AV conduction	
Second-degree block: Mobitz I	Progressive PR prolongation until QRS is dropped; <1:1 AV conduction	AVN
Second-degree block: Mobitz II	Random nonconducted beats (absence of QRS); <1:1 AV conduction	Below AVN
Third-degree block	AV dissociation; absence of AV conduction	AVN or below

AV, atrioventricular; AVN, atrioventricular node.

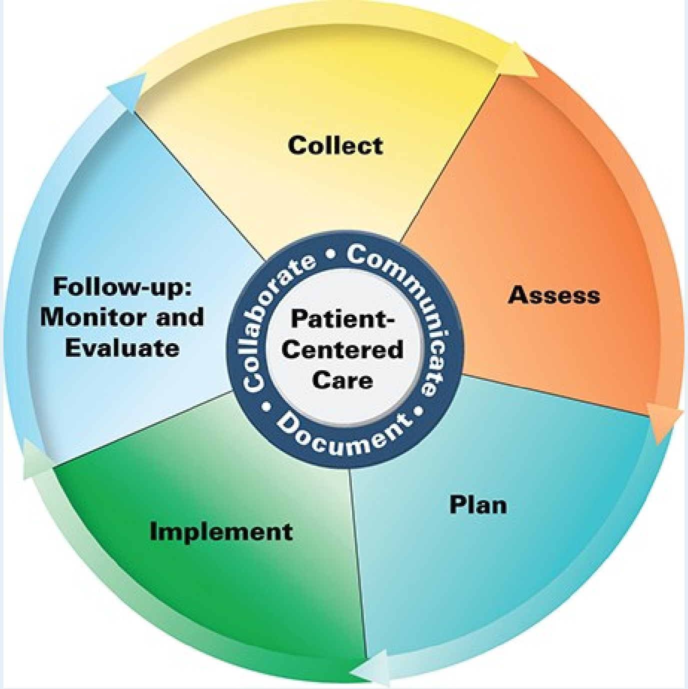
AV block may be found in patients without underlying SHD, such as trained athletes or during sleep when vagal tone is high. Also, AV block may be transient where the underlying etiology is reversible such as in myocarditis, myocardial ischemia, after CV surgery, or during medication therapy. β-Blockers, digoxin, or non-DHP CCBs may cause AV block, primarily in the AV nodal area. Class I AADs may exacerbate conduction delays below the level of the AV node (sodium-dependent tissue). In other cases, AV block may be irreversible, such as that caused by acute MI, rare degenerative diseases, primary myocardial disease, or congenital heart disease.

If patients with second-degree or third-degree AV block develop signs or symptoms of poor perfusion (eg, altered mental status, chest pain, hypotension, shock), IV atropine (0.5 mg given every 3-5 minutes, up to 3 mg total dose) should be administered.[79] If these patients do not respond to atropine, transcutaneous or transvenous pacing can be initiated. Sympathomimetic infusions such as epinephrine (2-10 μg/min) or dopamine (2-10 μg/kg/min) can also be used in the event of atropine failure and are particularly effective in sinus bradycardia/arrest and AV nodal block. An isoproterenol infusion (2-10 μg/min) may be considered if the patient does not respond to dopamine or epinephrine; however, this medication should be used with caution because of its vasodilating properties and ability to increase myocardial oxygen consumption (particularly during active MI). As would be expected, these medications usually do not help when the site of the AV block is below the AV node (eg, Mobitz II or trifascicular AV block) because their primary mechanism is to accelerate conduction through the AV node. If patients with bradycardia or AV block present with signs and symptoms of adequate perfusion, no acute therapy other than close observation is recommended.

Patients with chronic symptomatic AV block should be treated with the insertion of a permanent pacemaker.[93] Patients without symptoms can sometimes be followed closely without the need for a pacemaker. Patients with acute MI and evidence of new AV block or conduction disturbances will often require the insertion of a temporary transvenous pacemaker. AV block more commonly occurs as a complication of inferior wall MIs because of high vagal innervation at this site, and the coronary blood flow to the nodal areas usually supplies the inferior wall. However, the AV block may only be transient, obviating the need for permanent pacing.

PATIENT CARE PROCESS

Patient Care Process: Atrial Fibrillation



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex)
- History of present illness (eg, signs/symptoms of AF, duration of AF symptoms) and patient medical history
- Social history (eg, tobacco/ethanol use) and dietary habits including intake of vitamin K–containing foods (for warfarin)
- Current and previous medications including prescription, over-the-counter, aspirin/nonsteroidal anti-inflammatory medications, herbal products, and dietary supplements
- Objective data
    - Blood pressure (BP), ventricular rate (ie, heart rate), height, weight
    - Labs: electrolytes (potassium, magnesium), serum creatinine (SCr), hemoglobin, hematocrit, platelets, activated partial thromboplastin time, prothrombin time (PT), international normalized ratio (INR), thyroid function tests
    - 12-lead electrocardiogram and echocardiogram

Assess

- Hemodynamic instability (eg, systolic BP <90 mm Hg), evidence of decompensated heart failure, or angina
- Duration of AF symptoms (unknown, less than 48 hours, or greater than 48 hours)

- Left ventricular systolic function (ie, left ventricular ejection fraction)
- Risk of stroke (CHA_2DS_2-VASc score) and risk of bleeding (HAS-BLED score)
- Presence of potentially reversible causes of AF (eg, thyrotoxicosis, alcohol withdrawal, infection, electrolyte abnormalities [hypokalemia, hypomagnesemia])
- Ability/willingness to pay for anticoagulation treatment options
- Ability/willingness to obtain laboratory monitoring tests (eg, PT/INR [warfarin], SCr [direct oral anticoagulants (DOACs)])
- Potential medication interactions with anticoagulants and/or antiarrhythmics

Plan*

- Medication therapy regimen including anticoagulant, and/or antiarrhythmic as well as dose, route, frequency, and duration; see Figs. 40-7 and 40-8 and Tables 40-7, 40-8, 40-10, and 40-11.
- Monitoring parameters including efficacy (eg, ventricular rate, rhythm, PT/INR [warfarin], signs/symptoms of stroke) and safety (eg, proarrhythmia [ventricular tachycardia, torsades de pointes], sign/symptoms of bleeding, SCr); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, medication-specific information, monitoring/follow-up)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, PT/INR [warfarin], SCr [DOACs], adherence assessment (all medications), bleeding risk assessment [warfarin and DOACs], serum digoxin concentration [digoxin], pertinent laboratory/radiologic tests [amiodarone])

Follow-up: Monitor and Evaluate

- Ventricular rate and rhythm
- Symptoms
- Presence of adverse medication reactions (eg, bradycardia [ventricular rate control medications], bleeding [warfarin and DOACs], organ toxicities [antiarrhythmics]) (see Table 40-4)
- INR [warfarin only] (adjust warfarin dose as needed to maintain target INR in range of 2-3) and determine time in therapeutic range (TTR)
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Superventricular Tachycardias

Atrial Fibrillation/Flutter

General

- These arrhythmias are usually not directly life-threatening and do not generally cause hemodynamic collapse or syncope; 1:1 AFl (ventricular response approximately 300 beats/min) is an exception. Also, patients with underlying forms of heart disease who are heavily reliant on atrial contraction to maintain adequate cardiac output (eg, mitral stenosis, obstructive cardiomyopathy) display more severe symptoms of AF or AFl.

Symptoms

- Most often, patients complain of rapid heart rate/palpitations, chest pain, dyspnea, dizziness, and fatigue. Medical emergencies are severe HF (ie, pulmonary edema, hypotension) or AF occurring in the setting of acute MI.

ECG Findings

- AF is an irregularly irregular supraventricular rhythm with no discernible, consistent atrial activity (P waves). Ventricular rate is usually 90 to 170 beats/min and the pulse is irregular (Fig. 40-6).
- AFl is (usually) a regular supraventricular rhythm with characteristic flutter waves (or sawtooth pattern) reflecting more organized atrial activity. Commonly, the ventricular rate 150 beats/min (Fig. 40-6).

Paroxysmal Supraventricular Tachycardia Caused by Reentry

General

- This arrhythmia can be transient.

Symptoms

- Patients can complain of intermittent episodes of rapid heart rate/palpitations that abruptly start and stop, usually without provocation (but occasionally as a result of exercise). Severe symptoms include syncope. Often (in particular, those with AV nodal reentry), patients complain of a chest pressure or neck sensation. This is caused by simultaneous AV contraction with the right atrium contracting against a closed tricuspid valve. Life-threatening symptoms (syncope, hemodynamic collapse) are associated with an extremely rapid heart rate (eg, greater than 200 beats/min) and AF associated with an accessory pathway.

ECG Findings

- Most commonly, PSVT is a rapid, narrow QRS tachycardia (regular in rhythm) that starts and stops abruptly (Fig. 40-6). Atrial activity, although present, is difficult to ascertain on surface ECG because P waves are “buried” in the QRS complex or T wave.

CLINICAL PRESENTATION: Ventricular Arrhythmias

Premature Ventricular Contractions (PVCs)

General

- PVCs are not acutely life-threatening in a patient with a structurally normal heart and usually asymptomatic. A high frequency of PVCs (>20% of all beats) can cause ventricular dysfunction.

Symptoms

- Occasionally, patients will complain of palpitations or uncomfortable heartbeats. Since the PVC, by definition, occurs early and the ventricle contracts when it is incompletely filled, often the aortic valve will not open. The ensuing compensatory pause allows for an increase in left ventricular filling causing the next sinus beat have a more forceful contraction which can result in symptoms.

ECG Findings

- Premature, oddly shaped QRS complex that is unusually wide (Fig. 40-6).

Ventricular Tachycardia (VT)

General

- Patients can be asymptomatic or become hemodynamically compromised depending on their degree of underlying structural heart disease and rate of tachycardia.

Symptoms

- The symptoms of VT (monomorphic VT or TdP), if prolonged (ie, sustained), can vary from nearly completely asymptomatic to pulseless, hemodynamic collapse. Fast heart rates and underlying poor LV function will result in more severe symptoms. Symptoms of nonsustained, self-terminating VT also correlate with duration of episodes (eg, patients with 15-second episodes will be more symptomatic than those with three-beat episodes).

ECG Findings

- Wide QRS complexes at a rate >100 beats/min (Fig. 40-6).

Ventricular Vibrillation (VF)

General

- Cardiac output and blood pressure are not recordable.

Symptoms

- By definition, VF results in hemodynamic collapse, syncope, and cardiac arrest.

ECG Findings

- Lack of organized electrical activity, coarse fibrillation waves are seen. (Fig. 40-6).

EVALUATION OF THERAPEUTIC OUTCOMES

Generally, patients who suffer from tachyarrhythmias can be monitored for one or several possible therapeutic outcomes. Obviously, the presence or recurrence of any arrhythmia can be documented by electrocardiographic means (eg, surface ECG, Holter monitor, event monitor, or implantable loop recorder). Furthermore, patients may experience a decrease in blood pressure that may result in symptoms ranging from lightheadedness to abrupt syncope, depending on the rate of the arrhythmia and the status of the underlying heart disease. For some patients, the potential alteration in hemodynamics may result in death if the arrhythmia is not detected and treated immediately. Besides these clinical outcomes, many patients with tachyarrhythmias experience alterations in quality of life as a result of recurrent symptoms of the arrhythmia or from adverse drug reactions.

There are some therapeutic outcomes that are unique to certain arrhythmias. For instance, patients with AF or AFl need to be monitored for thromboembolism and complications of antithrombotic therapy (bleeding, medication interactions). Ultimately, the most important monitoring parameters for most patients fall into the following categories: (a) mortality (total and sudden cardiac death); (b) arrhythmia recurrence (duration, frequency, symptoms); (c) hemodynamic consequences (heart rate, blood pressure, symptoms); and (d) treatment complications (adverse drug reactions or need for alternative or additional medications, devices, surgery) (Table 40-16).

TABLE 40-16

Arrhythmia Outcomes

- Mortality
    - Total, all-cause mortality
    - Arrhythmia-related death (ie, sudden cardiac death)
- Signs and symptoms
    - Recurrences documented by electrocardiogram
    - Time to recurrence
    - Frequency of recurrences
    - Exercise tolerance
    - Lightheadedness
    - Blood pressure
    - Heart rate
- Surrogate markers used to determine efficacy
    - Number of premature ventricular complexes per day
    - Inducibility of tachycardia with programmed stimulation
    - Need for nonpharmacologic interventions (eg, ICD)
    - ICD shocks
    - Adverse drug reactions/treatment complications
- Quality of life
- Economics
- Arrhythmia specific (eg, systemic embolism in atrial fibrillation)

ICD, implantable cardioverter-defibrillator.

SELF-ASSESSMENT QUESTIONS

1. Which of the following best describes the primary ion channel inhibited by sotalol, the corresponding action potential phase affected, and its effects on the ECG?

   A. Sodium; phase 4 causing a prolongation of the QTc

   B. Sodium; phase 1 causing a widening the QRS

   C. Potassium; phase 2 causing a widening the QRS

   D. Potassium; phase 3 causing a prolongation of the QTc

2. Which of the following antibiotic classes should be avoided in combination with dofetilide?

   A. Fluoroquinolones

   B. Cephalosporins

   C. Penicillins

   D. Sulfonamides

3. A 57-year-old hospitalized patient develops atrial fibrillation with a rapid ventricular response (heart rate = 179 beats/min). Past medical history is significant for hypertension, angina, and thyrotoxicosis. Symptoms include fatigue and palpitations. Which of the following intravenous medications do you recommend as INITIAL management of the patient's atrial fibrillation?

   A. Digoxin to control his ventricular rate

   B. Esmolol to control his ventricular rate

   C. Ibutilide to restore sinus rhythm

   D. Amiodarone to restore sinus rhythm

4. In which of the following patients would it be the SAFEST to initiate flecainide?

   A. Thyrotoxicosis and obesity

   B. Asthma and heart failure

   C. Myocardial infarction and hyperlipidemia

   D. Coronary artery disease and severe left ventricular hypertrophy

5. A 54-year-old patient presents to the ER complaining of worsening palpitations, shortness of breath, and fatigue. Past medical history includes MI (5 months ago), HF (LVEF = 25% [0.25]), paroxysmal AF, and pulmonary fibrosis secondary to amiodarone (one year ago). Current medications include aspirin, enalapril, furosemide, carvedilol, atorvastatin, and rivaroxaban. Vital signs include BP 115/70 mm Hg, HR 72 beats/min. Pertinent labs include K+ 4.2 mEq/L (mmol/L), Mg 2.1 mEq/L (1.05 mmol/L), CrCl 32 mL/min (0.53 mL/s). ECG reveals: AF, HR 70 beats/min, QT interval 400 msec, QRS 94 msec. Successful electrical cardioversion is performed and the patient is now in sinus rhythm. The plan is to start chronic antiarrhythmic therapy to maintain him in sinus rhythm. Which of the following antiarrhythmic medication would be most appropriate to maintain him in sinus rhythm?

   A. Amiodarone

   B. Dofetilide

   C. Flecainide

D. Sotalol

6. For the acute management of AV nodal reentry and orthodromic AV reentry, which medication would be used first to restore normal sinus rhythm?

   A. Adenosine

   B. Procainamide

   C. Lidocaine

   D. Digoxin

7. A 19-year-old female with a history of WPW syndrome is seen in the ER. No other medical problems nor known heart disease is present. ECG shows atrial fibrillation (heart rate = 178 beats/min). The patient is hemodynamically stable. Which is the best intravenous medication to administer at this time?

   A. Adenosine

   B. Verapamil

   C. Procainamide

   D. Lidocaine

8. A 54-year-old man with a past medical history of asthma and migraines presents to the clinic complaining of dizziness and palpitations that have been occurring for the past 2 to 3 days. An ECG reveals that he is in atrial fibrillation (HR = 90 beats/min). Which option would be the most appropriate stroke prevention strategy for this patient?

   A. Aspirin

   B. Apixaban

   C. Clopidogrel

   D. No antithrombotic therapy is needed

9. Which patient will be at the highest risk of developing medication-induced torsades de pointes?

   A. Male with a history of stroke and taking amiodarone

   B. Male with a history of heart failure and taking flecainide

   C. Female with a history of hyponatremia and taking diltiazem

   D. Female with a history of myocardial infarction and taking dofetilide

10. A 52-year-old man, who has a history of skipping heartbeats, comes to the emergency department as the skipped beats are now accompanied with shortness of breath. Past medical history is insignificant. The ECG monitoring in the emergency department identifies non-sustained monomorphic ventricular tachycardia. Which of the following is the MOST APPROPRIATE treatment?

    A. Metoprolol

    B. Amiodarone

    C. Mexiletine

    D. Nifedipine

11. A 65-year-old man has a history of MI (6 months ago; current EF = 25% [0.25]) and recurrent ventricular tachycardia. During an electrophysiologic study, the patient experienced inducible ventricular tachycardia (rate = 240 beats/min), causing syncope. Which is the best treatment option for this patient's arrhythmia?

    A. Radiofrequency ablation of the accessory pathway

    B. Implantable cardioverter-defibrillator

    C. Initiate amiodarone therapy

    D. Increase the patient's β-blocker to the max dose

12. Which of the following comorbidities can be associated with the development of atrial fibrillation?

    A. Hypocalcemia

    B. Obstructive sleep apnea

    C. Asthma

    D. Hypothyroidism

13. Propafenone may cause which of the following ECG changes?

    A. Prolonged QRS interval

    B. Prolonged ST segment

    C. Shortened PR interval

    D. Shortened QT interval

14. A 78-year-old female is referred to the Electrophysiology clinic by their primary care doctor for atrial fibrillation. Past medical history is significant for HTN, asthma, and diabetes. The patient denies dizziness, fatigue, shortness of breath, palpitations, or chest pain. ECG demonstrates atrial fibrillation, HR 110 bpm, QTc 465ms, QRS 122ms. What would be the BEST treatment option for this patient?

    A. Diltiazem

    B. Flecainide

    C. Sotalol

    D. Amiodarone

15. Myocardial fibers that discharge spontaneously have which of the following present?

    A. Accelerated AV conduction

    B. Circus movement

    C. Abnormal automaticity

    D. Sinus arrhythmia

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Sotalol inhibits potassium channels; therefore, affecting phase 3 and leading to QTc prolongation. See "Pharmacologic Therapy" section. Table

40-2

2. **C.** Fluoroquinolone, macrolide, and azole anti-infectives can cause QTc prolongation, and are at greatest risk of causing torsades when given concomitantly with other QTc prolonging medications (ie, dofetilide). See Table 40-13.

3. **C.** This patient is hemodynamically stable with a potentially reversible cause of their atrial fibrillation, thyrotoxicosis; therefore, rate control would be the most appropriate answer (digoxin or esmolol). β-Blockers are considered first-line. If the patient is having a heart failure, exacerbation digoxin or amiodarone should be chosen. However, since this patient has thyrotoxicosis, amiodarone is not a good option. See "Atrial Fibrillation and Atrial Flutter General Approach to Treatment" section.

4. **A.** Because of the finds from CAST, Ic agents (flecainide and propafenone) should be avoided in patients with heart failure, history of myocardial infarction, or severe left ventricular hypertrophy.

5. **B.** Since this patient has heart failure, the treatment options are limited to two antiarrhythmics; amiodarone or dofetilide. Since the patient developed pulmonary fibrosis with amiodarone, this is no longer an option. The patient's baseline QTc is <440 msec and CrCl >30 mL/min (0.5 mL/s), so dofetilide is an acceptable choice. See "Atrial Fibrillation and Atrial Flutter General Approach to Treatment" section.

6. **A.** Adenosine is the best agent for terminating AV nodal reentry tachycardia or orthodromic AV reentry tachycardia. See a description of the management strategy under the section "Paroxysmal Supraventricular Tachycardia" for further details. See Fig. 40-11.

7. **C.** Procainamide is the best answer. This patient has a history of WPW (an accessory pathway) and has now developed a wide QRS, irregular arrhythmia, suggesting the patient may have atrial fibrillation that is conducting through the accessory pathway. IV digoxin, IV amiodarone, oral or IV β-blockers, diltiazem, and verapamil should be avoided in patients with preexcited AF as they may increase conduction over the accessory pathway leading to an increase in the ventricular rate and enhance the risk of provoking a life-threatening ventricular arrhythmia. See "Paroxysmal Supraventricular Tachycardia General Approach to Treatment" section.

8. **D.** This patient's CHA_2D_2SVASc score is 0. Therefore, the chronic use of an anticoagulant for stroke prevention is not warranted. See Fig. 40-7.

9. **D.** Individuals taking an antiarrhythmic that is a class Ia or III have a higher risk of developing torsades (amiodarone having the lowest risk); moreover, females are at a higher risk of torsades than males, and those with structural heart disease also carry a higher risk of developing torsades. See Tables 40-13 and 40-14 for further details.

10. **A.** For patients with nonsustained VT there are four treatment strategies based upon symptoms and underlying comorbidities: (a) conservative (ie, no AAD treatment beyond β-blockers); (b) empiric amiodarone; (c) ablation; and (d) aggressive (ie, electrophysiologic studies with possible insertion of an ICD). Since the patient has minimal symptoms, conservative management with metoprolol is the best option at this time. See Fig. 40-16.

11. **B.** The patient experienced an MI greater than 40 days ago, and his EF is less than 40% (0.40). Additionally, the patient experienced inducible ventricular tachycardia. Therefore, the best treatment option is an implantable cardioverter-defibrillator. See. Fig. 40-16

12. **B.** There are number of comorbidities, obstructive sleep apnea being a common one, that place individuals at risk for developing atrial fibrillation by creating structural and/or electrical changes in the atria. See "Atrial Fibrillation and Atrial Flutter" section.

13. **A.** Propafenone's primary action is on the sodium channels, but also works on beta receptors. Therefore, what can generally be seen on ECG when concentrations are high is a prolonged QRS interval and/or prolonged PR interval. See "Pharmacologic Therapy" section.

14. **A.** This patient is currently in atrial fibrillation with a heart rate of 110 beats per minute and is without symptoms. Thus, there is no true indication for rhythm control at this time, and rate control is the best option with a heart rate goal <110 beats per minute. Moreover, the patient's QTc is 465 ms, which is too long for the initiation of sotalol. Amiodarone would not be the first option due to its side effect profile. See "Atrial Fibrillation and Atrial Flutter General Approach to Treatment "B" Better Symptom Management" section.

15. **C.** There are several mechanisms that cause arrhythmias with abnormal automaticity, triggered activity, and reentry are the main types. When an impulse is said to generate in an area of the heart that does not normally fire on its own the mechanism is typically from abnormal automaticity. See

"Pathophysiology Abnormal Conduction" section.

Chapter 41: Cardiopulmonary Arrest

Jeffrey F. Barletta

KEY CONCEPTS

KEY CONCEPTS

1 High-quality cardiopulmonary resuscitation with minimal interruptions in chest compressions should be delivered to all patients following cardiac arrest.

2 The American Heart Association (AHA) algorithm for basic life support emphasizes circulation, airway, and breathing, forming the mnemonic “CAB.”

3 The purpose of using vasopressor therapy following cardiac arrest is to augment coronary and cerebral perfusion pressures.

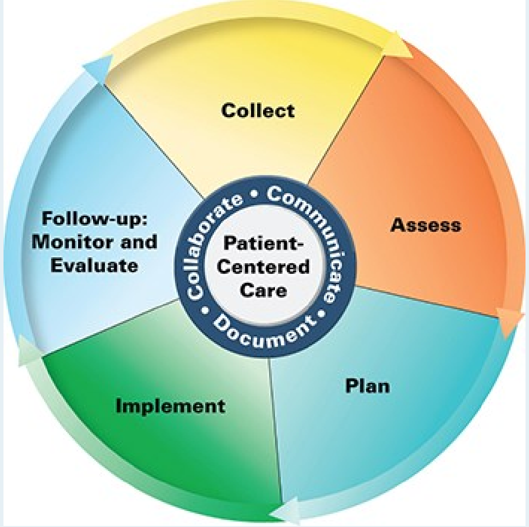
4 Successful treatment of both pulseless electrical activity (PEA) and asystole largely depends on determining the underlying cause. Epinephrine should be administered as soon as possible.

5 Following the return of spontaneous circulation (ROSC) from a cardiac arrest, patient management should be directed toward the postcardiac arrest syndrome. Post-resuscitation care often requires several interventions including, but not limited to, targeted temperature management, stabilization of respiratory and cardiovascular systems, interventions to achieve hemodynamic stability, control of blood glucose, and treatment of seizures and infectious complications.

6 Intravenous (IV) administration is the preferred route for medication delivery; intraosseous (IO) can be considered when IV access cannot be readily obtained or is not feasible.

PATIENT CARE PROCESS

Patient Care Process for Cardiac Arrest



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect*

- Patient characteristics (eg, sex, age)
- Patient medical history (if available)
- Current and past medications that could have contributed to the arrest or serve as a clue to the underlying medical history
- Objective data
    - Presence of a pulse
    - Cardiac rhythm

Assess*

- Is the patient responsive?
- Is there a pulse present?
- Are the electrocardiogram (ECG) leads correctly placed on the patient?
- Is the rhythm shockable?

Plan*

- Activate emergency medical services (EMS) and obtain an automated external defibrillator (AED) if one is nearby (for out-of-hospital arrest) (Fig. 41-2)
- Call for "code blue" and obtain crash cart (for in-hospital arrest)
- Immediately begin chest compressions and follow basic life support (BLS) algorithm
- Administer electrical therapy (ie, defibrillation) if indicated
- Drug therapy per advanced cardiac life support (ACLS) algorithm if indicated (Table 41-1)
- Monitor for the return of spontaneous circulation (ROSC), cardiac rhythm, and pulse

Implement*

- Perform high-quality chest compressions with minimal interruptions
- Administer defibrillations and drug therapy as indicated by cardiac rhythm

Follow-up: Monitor and Evaluate*

- Monitor end-tidal CO_2 as an indicator of cardiopulmonary resuscitation (CPR) quality
- Implement postresuscitative care plan
- ECG and percutaneous coronary intervention (PCI) when an acute coronary syndrome is suspected
- Review patient history for identification of other contributors or underlying cause of the arrest
- Diligent monitoring of blood pressure, oxygen saturation, temperature, urine output, and glucose
- Evaluate and monitor for seizure

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Review the American Heart Association (AHA) algorithms for BLS and ACLS. Create a table that lists the medications used during a cardiac arrest and after the ROSC, when those medications might be used, and the intended purpose of each medication. All guidelines for cardiopulmonary resuscitation and emergency cardiac care can be found at https://tinyurl.com/zy2efpq.

INTRODUCTION

Cardiac arrest is defined as the cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation (eg, a detectable pulse, unresponsiveness, and apnea).[1] While there is wide variation in the reported incidence of cardiac arrest, there are more than 350,000 people in the United States who are assessed by EMS for a suspected out-of-hospital cardiac arrest each year.[1] Survival to hospital discharge following out-of-hospital cardiac arrest is only 10.5% and survival with good neurologic function is even lower.[1] While there has been a minimal change over the last 40 years, the survival rate for out-of-hospital cardiac arrest improved slightly during the last reported observation period between 2005 and 2012.[2] This improvement was seen in both prehospital and in-hospital survival.

The incidence of in-hospital cardiac arrests is roughly 10 per 1,000 hospital admissions in the United States annually.[1] Similar to out-of-hospital arrests, some progress has also been made over the past decade with in-hospital cardiac arrests, where survival rates to hospital discharge have increased from 17% in 2000 to 27% in 2019.[1] Survival rates are substantially higher in victims with a shockable rhythm (ie, those who are treated with electrical defibrillation).

EPIDEMIOLOGY

Cardiac arrest can arise from either cardiac or noncardiac origins (eg, submersion, asphyxia, trauma, and overdose). In adult patients, cardiac arrest usually results from the development of an arrhythmia. Historically, ventricular fibrillation (VF) and pulseless ventricular tachycardia (PVT) have been the most common initial rhythms seen in out-of-hospital arrests, but these are now seen in less than one-quarter of cases.[1] In fact, data from the Cardiac Arrest Registry to Enhance Survival (CARES) project reported asystole to be the most common presenting rhythm (53%), which is similar to other registry data whereby nonshockable rhythms (ie, asystole, PEA) were more prevalent.[3] It is unclear why there has been a change in the types of arrhythmias that most commonly lead to cardiac arrest. Possible explanations include the increasing incidence of noncardiac causes of arrest that present with apnea leading to bradycardia and then pulseless electrical activity (PEA) or asystole. A second explanation might be the increasing role of implantable pacemakers and defibrillators.[4] Finally, beta-blockers and ACE inhibitors may shorten the duration of VF, and the expanded use of these drug classes for ischemic heart disease and heart failure may account for the increased occurrence of non-VF/PVT rhythms.[4] This change in the presenting rhythm types is concerning because survival rates to hospital discharge are substantially higher with shockable rhythms like VF and PVT (26%) compared to nonshockable rhythms like PEA (10%) and asystole (2%).[3]

A similar finding has been observed with in-hospital cardiac arrest. One study using the “Get With The Guidelines-Resuscitation” registry reported that 79% of patients had an initial rhythm of asystole or PEA and only 21% had VF or PVT.[5] Survival rates were 12.2% for asystole/PEA and 35% for VF/PVT.

In pediatric patients, cardiac arrest typically results from respiratory failure and asphyxiation. As such, the initial rhythm most often encountered in out-of-hospital arrest is PEA or asystole. Similar to the adult population, survival rates have increased over the past decade from 28% in 2000 to 52% in 2019 according to one registry.[1] Survival rate with out-of-hospital pediatric arrests is roughly 15% and is lower in infants when compared to children and adolescents.[1] Survival following in-hospital cardiac arrest is much higher (45%), and most survivors have a favorable neurologic outcome (89%).[6]

ETIOLOGY

The most common clinical finding in adult patients who suffer cardiac arrest is coronary artery disease, accounting for roughly 75% of sudden cardiac deaths.[7] Other causes of sudden cardiac death include cardiomyopathies, valvular heart disease, myocarditis, left ventricular hypertrophy, primary electrical heart disease, and noncardiac causes. Unfortunately, in many patients (up to 69%), cardiac arrest is the first clinical sign of coronary artery disease with no preceding signs or symptoms.[7]

In pediatric patients, cardiac arrest is often the terminal event of respiratory failure or progressive shock.[8] Out-of-hospital cardiac arrests frequently are associated with trauma, sudden infant death syndrome, drowning, poisoning, choking, severe asthma, and pneumonia. In-hospital cardiac arrests, on the other hand, are associated with sepsis, respiratory failure, drug toxicity, metabolic disorders, and arrhythmias.

PATHOPHYSIOLOGY

There are two distinct pathophysiologic conditions associated with cardiac arrest. The first is primary cardiac arrest whereby arterial blood is fully oxygenated at the time of arrest. As forward blood flow ceases, arterial blood oxygenation remains normal for about 10 minutes and subsequently declines due to the lack of ventilation.[9] Alternatively, respiratory failure can lead to severe hypoxemia, hypotension, and secondary cardiac arrest. It is important to identify the underlying pathophysiology as different treatment approaches are required.[9]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Cardiopulmonary Arrest

General:

- Cardiac arrest is characterized by the cessation of cardiac mechanical activity. General signs and symptoms are consistent with a sudden cessation of circulation.

Symptoms (occurring prior to the event)

- Anxiety
- Crushing chest pain
- Nausea
- Vomiting
- Diaphoresis

Signs

- Apnea
- Hypotension
- Lack of a detectable pulse
- Cyanosis
- Cold, clammy extremities
- Loss of consciousness
- Syncope

TREATMENT

Desired Outcome

The global goals of resuscitation are to preserve life, restore health, relieve suffering, limit disability, and respect the individual's decisions, rights, and privacy.[10] Providing high-quality CPR and quickly achieving the ROSC with effective perfusion and ventilation can minimize hypoxic damage to vital organs and achieve these goals. Survival to hospital discharge with good neurologic function should be the primary treatment outcome sought by clinicians. Survival to hospital discharge in a vegetative or comatose state cannot be classified as a success and can impose a tremendous economic burden on the healthcare system.

The presence of a healthcare advanced directive allows patients to communicate their wishes and preferences regarding medical care and may lead to a "do not attempt resuscitation" order. These orders should explicitly state the resuscitation interventions that are to be performed and should have been clearly communicated by the patient, their family, or a surrogate decision-maker.

General Approach to Treatment

Cardiopulmonary Resuscitation

Resuscitation techniques have been studied for many years. In 1960, Kouwenhoven described positive outcomes in 14 of 20 patients with in-hospital cardiac arrest who were given closed chest compressions at a rate of 60 per minute.[11] Following the publication of this landmark article, chest compressions integrated with expired air ventilation (ie, mouth-to-mouth) became the fundamentals of basic life support known as the “ABC’s.”[11]

Cardiopulmonary resuscitation employs chest compressions to restore threshold blood flows, particularly to the heart and brain. There are two proposed explanations to describe how chest compression improves blood flow during CPR.[11] The original explanation is known as the cardiac pump theory whereby compression of the heart between the sternum and vertebrae creates forward flow. However, echocardiography during chest compressions has revealed that the left ventricular size does not always change and the mitral valve may not close.[11] The second explanation is the thoracic pump theory whereby intrathoracic pressure changes during chest compressions promote blood flow while the heart merely acts as a passive conduit. It is likely that both cardiac compression and intrathoracic pressure changes contribute.

Since 1966, the AHA has published guidelines for the treatment of cardiac arrest in 5-year increments. In 2015, this process transitioned to an online format that is continuously updated in an attempt to expedite the most current evidence-based practices to the bedside. The most recent document, the 2020 guidelines, reflects alignment with the International Liaison Committee on Resuscitation and reviews scientific questions considered of greatest significance and new evidence.[12]

①High-quality CPR continues to be emphasized in the latest guidelines published by the AHA. Clinicians must focus on proper technique, including adequate rate and depth of compressions, allowing full chest recoil after each compression, avoiding excessive ventilation, and minimizing interruptions. There is an association between survival to hospital discharge and chest compression rate (optimally between 100 and 120 beats/minute), chest compression depth (optimally 40–54 mm), and chest compression fraction (optimally the proportion of resuscitation time without spontaneous circulation when chest compressions are administered should be ≥60%).[13] Unfortunately, the provision of CPR is frequently sub-optimal, particularly when rescuers become fatigued.[14] Real-time audiovisual feedback mechanisms during CPR have been encouraged. These can include voice prompts (eg, “push harder”), visual displays (for compression quality), audio prompts (eg, metronome to guide CPR rate) or an analog “clicker” feedback device that emits a noise and sensation when sufficient pressure is applied during CPR. One study reported a 25% absolute increase in survival to hospital discharge with the use of an analog “clicker” device.[15]

The 2020 guidelines continue to emphasize the “chain of survival” to highlight the treatment approach and illustrate the importance of a timely response. The updated guidelines include two separate chains (one for out-of-hospital cardiac arrest and another for in-hospital cardiac arrest), both having six links.[16] The two chains reflect the differences in the steps needed to respond to a cardiac arrest in the in-patient and out-patient settings. The links in each chain of survival are as follows:

Out-of-hospital

1. Activation of emergency response
2. High-quality CPR
3. Defibrillation
4. Advanced resuscitation
5. Postcardiac arrest care
6. Recovery

In-hospital

1. Early recognition and prevention
2. Activation of emergency response
3. High-quality CPR
4. Defibrillation

5. Postcardiac arrest care
6. Recovery

Activation of emergency response systems and early recognition and prevention are the first links in the chain of survival for out-of-hospital and in-hospital cardiac arrests, respectively. For out-of-hospital cardiac arrests, activation of emergency response systems allows for dispatcher-assisted CPR whereby instructions are delivered to a community bystander over the telephone. Further, mobile phone technology is increasingly being used to summon nearby bystanders who might assist with out-of-hospital events. For in-hospital cardiac arrests, clinical deterioration typically precedes a cardiac arrest; therefore, early warning systems based on vital sign abnormalities, advanced scoring systems, or staff concerns are advised.[17] High-quality CPR and rapid defibrillation for shockable rhythms are the foundation for good resuscitation outcomes after cardiac arrest.[18] Advanced resuscitation interventions, which include pharmacotherapy, advanced airways, and extracorporeal CPR, may improve outcomes in special situations. Postcardiac arrest care consists of important therapies such as targeted temperature management, mechanical ventilation, and other crucial critical care support modalities including pharmacotherapy. Recovery is the newest link added to both chains of survival. Recognizing that recovering from cardiac arrest continues long after hospital discharge, measures to support physical, cognitive, emotional well-being, and psychosocial needs are recommended.[16]

Sequence of Resuscitation

Basic Life Support

② The mnemonic for the CPR sequence is "CAB" which stands for circulation, airway, and breathing. Historically, BLS and ACLS providers have been taught the mnemonic, "ABC." The change to CAB was made to stress the importance of maintaining blood flow to the heart and brain and to avoid delays or interruptions to chest compressions.

When first encountering a cardiac arrest victim, the initial action is to determine if the patient is responsive. If there is no response, the rescuer should immediately activate the EMS team, obtain (or call for) an AED, and then immediately start CPR with chest compressions. A cardiac arrest victim will be unresponsive, and it can be difficult for rescuers to determine if the victim is breathing normally. Thus, "look, listen, and feel" for respirations is no longer recommended as part of the initial assessment.[16] Similarly, lay rescuers may have difficulty in detecting a pulse leading to delays in chest compressions; thus, a pulse check is not recommended. In situations where the rescuer is unsure if the victim has suffered a cardiac arrest (eg, when agonal breathing is present), CPR should be promptly initiated. The risk of chest compressions in a patient who is not in cardiac arrest is low compared to the high potential for harm should CPR be withheld in a pulseless victim.[16] Healthcare providers could assess for a pulse but take no more than 10 seconds to do so. If one is not detected within this short time frame, then chest compressions should be immediately initiated.[16]

The prompt provision of chest compressions is of paramount importance, and rescuers should attempt them regardless of rescuer experience or skill. High-quality chest compressions should be delivered at a rate of 100 to 120 compressions per minute, with adequate depth (at least 2 in. [~50 mm] in an adult), while allowing full chest recoil and minimizing any interruptions.

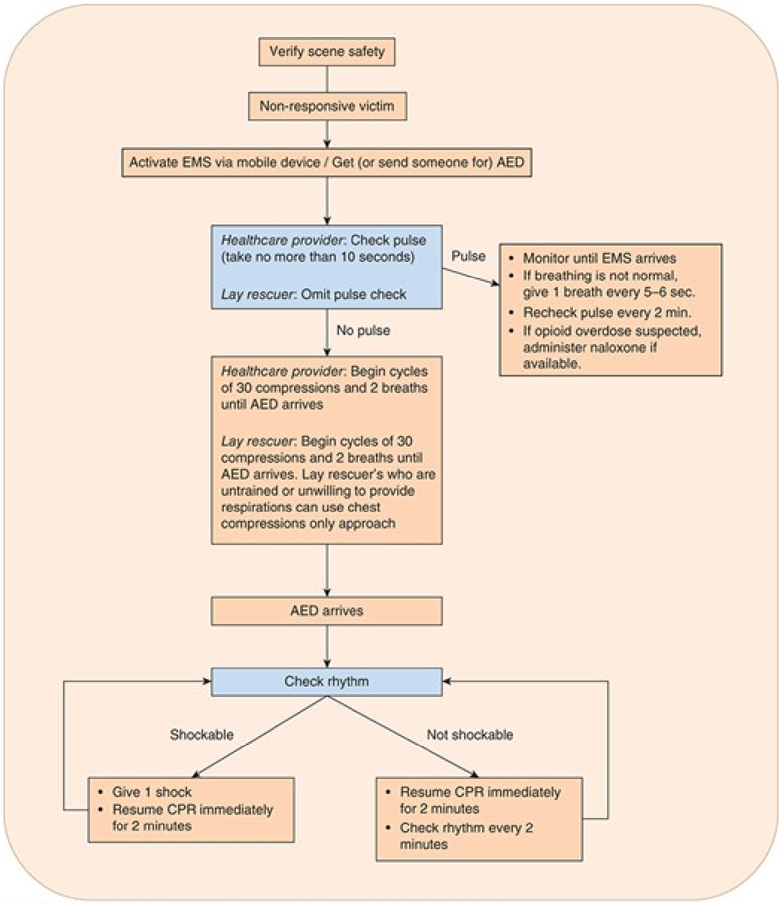
While the provision of high-quality chest compressions is essential, the role of ventilation (ie, rescue breaths) in the initial management of cardiac arrest is less clear. Chest compressions deliver a small but critical amount of oxygen to the brain and myocardium. Cerebral and coronary perfusion pressure (CPPs), however, build up slowly once chest compressions are begun. These perfusion pressures are lost if chest compressions are stopped to deliver mouth-to-mouth ventilation resulting in reduced blood flow and decreased effectiveness of CPR. In fact, the time it takes to deliver two rescue breaths has been reported to range between 10 seconds and 16 seconds based on the experience of the rescuer.[19] These interruptions can be significant given the proportion of time chest compressions are being performed during CPR is associated with improvements in survival.[20] Along with concerns related to interruptions with chest compressions, some lay rescuers may be reluctant to initiate CPR at all, if they are uncomfortable with administering rescue breaths. These principles led to the origin of chest compression-only CPR. Chest compression-only CPR has been associated with increased survival compared to conventional CPR and no bystander CPR.[21] However, if ventilations are withheld, arterial oxygen content will decrease as CPR duration increases.

Based on a recent systematic review, CPR recommendations have been updated.[16,22] Chest compression-only CPR is appropriate for lay rescuers who are untrained or unwilling to provide respirations. Lay rescuers who are trained, able, and willing to give rescue breaths should do so using a compression to breath ratio of 30:2. For EMS-delivered CPR, providers should perform CPR in cycles of 30 compressions and 2 breaths or alternatively 1 breath every 6 seconds for asynchronous ventilation during continuous chest compressions.

In all cases, CPR should continue until an AED arrives. The AED leads should be immediately placed on the victim so that the device can determine if the rhythm is shockable. If so, then one shock should be delivered, and CPR immediately resumed for 2 minutes or until prompted by the AED for another rhythm check. If the rhythm is not shockable, CPR should resume immediately for 2 minutes or until prompted by the AED. This cycle should be continued until advanced life support providers take over or the victim starts to move (Fig. 41-1). In settings where more than one rescuer is present, rotating the provider performing chest compressions should occur every 2 minutes to minimize rescuer fatigue, which can lead to poor quality chest compressions.

FIGURE 41-1

Treatment algorithm for adult cardiac arrest: Basic life support (BLS).



Verify scene safety
Non-responsive victim
Activate EMS via mobile device / Get (or send someone for) AED
Healthcare provider: Check pulse (take no more than 10 seconds)
Lay rescuer: Omit pulse check
Pulse
• Monitor until EMS arrives
• If breathing is not normal, give 1 breath every 5–6 sec.
• Recheck pulse every 2 min.
• If opioid overdose suspected, administer naloxone if available.
No pulse
Healthcare provider: Begin cycles of 30 compressions and 2 breaths until AED arrives
Lay rescuer: Begin cycles of 30 compressions and 2 breaths until AED arrives. Lay rescuer's who are untrained or unwilling to provide respirations can use chest compressions only approach
AED arrives
Check rhythm
Shockable
Not shockable
• Give 1 shock
• Resume CPR immediately for 2 minutes
• Resume CPR immediately for 2 minutes
• Check rhythm every 2 minutes

Defibrillation is crucial for survival in cardiac arrests caused by VF or PVT, especially when administered as soon as possible after the onset of the arrest. When the duration of VF/PVT is more prolonged (eg, an unwitnessed or an unmonitored arrest due to the arrival of an AED), the efficacy of defibrillation is compromised due to depletion of myocardial oxygen reserves and the presence of global tissue ischemia. A short period of CPR to replenish blood flow (via chest compressions) and "flush out" deleterious metabolic factors may be beneficial. Intentional, prolonged periods of chest compressions (90-180 seconds) before defibrillation have not been shown to improve outcomes.[22] Therefore, in unmonitored cardiac arrests, a brief period of CPR can be administered while the defibrillator is being obtained and readied for use.

CPR can be physically demanding, and rescuer fatigue can lead to poor quality chest compressions. As a result, mechanical devices have been developed with the aim of providing consistent high-quality chest compressions that can be sustained throughout the entire arrest period. Animal studies have shown that cerebral blood flow is greater with these devices compared to manual compression. Studies in humans, however, have not demonstrated improved survival or survival with good neurological function.[16] Lack of survival benefit may be due to time delays associated with their deployment. While the routine use of mechanical CPR devices is not recommended, their use may be considered in specific settings where the delivery of high-quality manual compressions may be challenging such as ambulance or helicopter transfers.

Advanced Cardiac Life Support

Once EMS or other ACLS certified providers arrive, additional therapy may be given. Either a bag-mask device or an advanced airway such as a supraglottic device or an endotracheal tube or a supraglottic device may be utilized to provide ventilation. If an advanced airway is used, supraglottic airways are preferred in settings with low tracheal intubation success rates or when minimal training opportunities exist. Once an airway is established, one provider can deliver 1 breath every 6 seconds while continuous chest compressions are being performed by a second provider.

Monitoring of CPR quality may be performed using end-tidal carbon dioxide ($ETCO_2$) monitoring or arterial blood pressure assessment when feasible. $ETCO_2$ is the concentration of carbon dioxide in exhaled air at the end of expiration. During cardiac arrest, the level of $ETCO_2$ decreases because there is no flow through the pulmonary circulation. Thus, a persistently low $ETCO_2$ (ie, <10 mm Hg [1.3 kPa]) during CPR in intubated patients makes ROSC unlikely.[16] One large study using the "Get with the Guidelines-Resuscitation" registry reported a higher rate of ROSC when physiologic monitoring with either $ETCO_2$ or arterial blood pressure was performed.[23] Physiologic monitoring with $ETCO_2$ or arterial blood pressure is, therefore, suggested.

If not already placed, an AED should be attached and access for administration of parenteral medications should be obtained. Cardiac arrest victims who are in VF or PVT should be administered one shock with the immediate resumption of chest compressions.[16] If there is still a shockable rhythm, then an additional shock should be delivered every 2 minutes. After two cycles, epinephrine is indicated. Chest compressions continue while medications are being prepared and administered. This cycle is repeated until either a pulse is obtained with effective circulation, the rhythm changes or the patient expires. If the cardiac rhythm is not deemed to be shockable, then the patient is likely to be in either asystole or PEA. In this circumstance, epinephrine should be administered as soon as possible and the rescuer must consider reversible causes (Fig. 41-2).

Extracorporeal CPR is the use of cardiopulmonary bypass during the resuscitation of a cardiac arrest victim. It entails the rapid deployment of veno-arterial extracorporeal membrane oxygenation (ECMO) to provide circulatory support when conventional CPR is unsuccessful. The goal is to provide end-organ support while reversible conditions are addressed. ECMO is a highly specialized therapy that requires a dedicated team of specialized experts. While there is insufficient evidence to support the routine use of extracorporeal CPR, it may be considered as rescue therapy if there is a reversible cause of the arrest.

Ventricular Fibrillation / Pulseless Ventricular Tachycardia

Nonpharmacologic Therapy

Ventricular fibrillation and PVT are “shockable rhythms.” Thus, defibrillation combined with cardiopulmonary resuscitation are crucial components in the care of cardiac arrest victims. CPR provides critical blood flow to the heart and brain, prolongs the time VF/PVT is present (prior to the deterioration to asystole), and increases the likelihood that a shock will terminate VF/PVT and result in a rhythm compatible with life. The brain can normally survive for only 3 to 5 minutes before damage occurs; thus, delays in the provision of CPR can worsen outcomes. With immediate CPR, the rate of survival decreases by 3% to 4% per minute between the onset of the arrest and defibrillation.[24] Without bystander CPR, survival rates decrease by 7% to 10% per minute.[24] In effect, CPR can increase the likelihood of survival threefold from arrest to survival. Basic CPR alone is not likely to terminate VF/PVT; electrical defibrillation is often necessary to restore a cardiac rhythm.

Pre-hospital systems of care remain an area of emphasis for communities to improve outcomes following a cardiac arrest.[18,25] In one large study, the rate of bystander CPR was only 34% while only 2.3% of cardiac arrests utilized an AED.[26] Community programs are necessary to provide education and raise awareness of the importance of early CPR. Examples of these programs include dispatcher-assisted CPR, whereby instructions are provided via mobile telephone. Mobile phone technology can also be used to alert a bystander that an arrest has occurred within their geographic vicinity. Education programs on the use of public access defibrillators can promote the early use of ADE’s by lay responders. One systematic review reported survival rates of 53% with the early use of defibrillation using an AED administered by lay responders.[27] Finally, specialized cardiac arrest centers with experienced clinicians who are well versed in the evidence-based management of post-resuscitation care could be important. While data reporting improvements in survival to hospital discharge are mixed, these centers often have the capability to perform ECMO and other advanced forms of organ support.

Pharmacologic Therapy

Vasopressors

Vasopressors continue to be the first pharmacologic agents administered in the setting of cardiac arrest despite limited evidence demonstrating improvements in neurologic function postarrest. Nevertheless, vasopressors have been associated with an increased rate of ROSC and play a major role in the pharmacotherapy of cardiac arrest.

③ The primary goal of vasopressor therapy is to augment low coronary and cerebral perfusion pressures encountered during CPR. Chest compressions can improve blood flow to the heart and the brain but only to about 25% of normal. Even with optimally performed chest compressions, CPPs are only 10 to 15 mm Hg, and systolic arterial pressure is rarely above 80 mm Hg.[28] Clinical data have indicated that ROSC is unlikely when the CPP is less than 15 mm Hg.[29,30] Vasopressors, therefore, work to increase these pressures through their vasoconstrictive properties.

Epinephrine continues to be the drug of first choice for the treatment of VF, PVT, asystole, and PEA. Epinephrine is an alpha- and beta-receptor agonist causing vasoconstriction as well as increasing the rate and forcefulness of heart contractions.

In a large randomized controlled trial of patients with out-of-hospital cardiac arrest (18% with VF or PVT), epinephrine was compared to saline placebo.[31] Epinephrine use was associated with a significant improvement in survival at 30-days, and the benefit was more pronounced in patients with a nonshockable initial rhythm. Favorable neurologic outcome (at discharge), however, was no different in the epinephrine group. In fact, there were more patients with severe neurologic impairment with epinephrine. A second randomized, controlled trial compared epinephrine with placebo in patients with cardiac arrest (fewer than 50% had VT or PVT as the initial rhythm).[32] ROSC and survival to hospital admission were significantly higher with epinephrine but there was no difference in survival to hospital discharge. Similar to the previous trial, the effect of epinephrine was greater in those with non-shockable rhythms. A subsequent meta-analysis found that epinephrine was associated with significant improvements in ROSC, survival to hospital discharge, and survival at 30 days.[33] There was no difference, however in neurological outcome at discharge. When stratified by initial rhythm, these differences were greater in the cohort of patients with nonshockable rhythms. Most notably, survival at 30-days was significant with nonshockable rhythms but not with VF/PVT.

Several large observational studies have evaluated the impact of epinephrine on survival. One large registry study failed to demonstrate a survival benefit with prehospital administration of epinephrine.[34] Despite a significant improvement in ROSC with epinephrine, 1-month survival and survival with good neurologic function were both lower in patients who received epinephrine. A second study evaluated outcomes in patients with witnessed out-of-hospital cardiac arrest.[35] Epinephrine was associated with improvements in survival at 1 month or discharge in patients with VF/PVT but there was no difference in neurologically intact survival.

Timing of epinephrine administration could be an important confounder and contribute to the heterogeneity observed with survival data. In a posthoc analysis of data from the largest randomized controlled trial conducted to date, the odds of ROSC decreased in both epinephrine and placebo groups over time, but at a greater rate with placebo.[36] A second study revealed survival and favorable functional status decreased with delayed administration.[37] Specifically, ROSC was highest in the cohort who received epinephrine within 5 minutes after the provision of advanced life support. Similarly, other studies have reported the association with delays in epinephrine administration and a reduction in the odds of survival and the odds of hospital discharge with good neurologic function are reduced.[38–42]

Despite notable improvements in survival, epinephrine does not improve survival with good neurologic function, which may be related to its mechanism of action. Epinephrine causes alpha-mediated vasoconstriction which increases coronary perfusion but may also decrease perfusion to other vital organs. Animal research has linked epinephrine to a decrease in cerebral microvascular blood flow and an increase in brain tissue ischemia during and after CPR.[43] One study in humans measured cerebral oxygenation in patients who experienced an in-hospital cardiac arrest, before-and-after epinephrine administration.[44] A small increase in cerebral oxygenation (1.4%) was noted but the clinical importance of this small change is questionable. Alternatively, the negligible effect on neurologic function could be due to the brain being more sensitive to ischemia compared to other organs and less able to recover once ROSC is achieved.

Epinephrine also stimulates beta-receptors, which can increase myocardial oxygen demand, impair lactate clearance, and contribute to postresuscitation myocardial dysfunction.[45] Studies have compared epinephrine with other adrenergic agonists with less beta-activity (eg, pure alpha-1 agonists such as phenylephrine and methoxamine or more potent alpha-agonists like norepinephrine).[46] When compared to pure alpha-1 agonists, there is no advantage in terms of long-term survival. One potential reason could be the potent alpha-2 effects of epinephrine and the fact that these receptors lie extrajunctionally in the intima of the blood vessels making them more accessible to circulating catecholamines. Furthermore, during ischemia, the number of postsynaptic alpha-1-receptors decreases which suggests a greater role for alpha-2 agonists during CPR. Epinephrine has also been compared with norepinephrine, a potent alpha-agonist (both alpha-1 and alpha-2) with some beta-1 effects. In the only large-scale randomized, double-blind, prospective trial comparing epinephrine and norepinephrine use in patients with an out-of-hospital cardiac arrest, there were no significant differences in ROSC, hospital admission, or discharge.[47] A second, smaller study demonstrated higher resuscitation rates with norepinephrine compared to epinephrine (64% vs 32%) but no significant difference in survival to hospital discharge.[48]

The recommended dose for epinephrine is 1 mg administered by intravenous (IV) or intraosseous (IO) injection every 3 to 5 minutes[16] (Table 41-1). The recommended dose for epinephrine was derived from animal studies (0.1 mg/kg in a 10 kg dog) and equates to approximately 0.015 mg/kg for a 70 kg human.[49] Animal studies have demonstrated a positive dose-response relationship with epinephrine, suggesting that higher doses might improve hemodynamics and resuscitation success.[46] However, human studies have reported increased morbidity with high-dose epinephrine. The hemodynamic findings are consistent with catecholamine toxicity, including decreased cardiac indices, left ventricular dysfunction, and decreased oxygen delivery. This discrepancy between animal and human studies could be related to most victims of cardiac arrest having coronary artery disease, which is not encountered in an animal model. Additionally, atherosclerotic plaques in humans can aggravate the balance between myocardial oxygen supply and demand, and the interval from arrest to treatment is longer in human studies than that encountered in an animal model. Thus, high-dose epinephrine is not recommended for routine use in cardiac arrest.

TABLE 41-1

Evidence-Based Recommendations

Recommendations	Recommendation Grades[a]
Epinephrine	
Epinephrine is recommended for patients in cardiac arrest	Class I, LOE B-R
Standard dose epinephrine (1 mg IV/IO every 3-5 minutes) may be reasonable for patients with cardiac arrest	Class IIa, LOE B-R
In patients with cardiac arrest with a shockable rhythm, it may be reasonable to administer epinephrine after initial defibrillation attempts have failed	Class IIb, LOE C-LD
In patients with cardiac arrest with a nonshockable rhythm, it may be reasonable to administer epinephrine as soon as feasible after the onset of cardiac arrest	Class IIa, LOE C-LD
High-dose epinephrine is not recommended for routine use in cardiac arrest	Class 3, LOE B-R
Vasopressin	
Vasopressin alone or in combination with epinephrine may be considered but offers no advantage as a substitute for standard dose epinephrine	Class IIb, LOE C-LD
Amiodarone	
Amiodarone may be considered in patients with VF/PVT unresponsive to defibrillation	Class IIb, LOE B-R
Lidocaine	
Lidocaine may be considered in patients with VF/PVT unresponsive to defibrillation	Class IIb, LOE B-R
Magnesium	
Magnesium is not routinely recommended for VF/PVT	Class III: No benefit, LOE B-R
Thrombolysis	
Thrombolysis may be considered when cardiac arrest is suspected to be caused by pulmonary embolism	Class IIb, LOE C-LD
Sodium bicarbonate	
Routine use of sodium bicarbonate is not recommended	Class III: No benefit, LOE B-R
Corticosteroids	
For out-of-hospital cardiac arrest, use of corticosteroids during CPR is of uncertain benefit	Class IIb, LOE C-LD

CPR, cardiopulmonary resuscitation; IV, intravenous; IO, intraosseous; VF, ventricular fibrillation; PVT, pulseless ventricular tachycardia; LOE, level of evidence.

[a]Key for evidence-based classifications:

Class of recommendations:

- Class I (Strong). Benefit >>>Risk
- Class IIa (Moderate). Benefit >> Risk
- Class IIb (Weak). Benefit ≥ Risk
- Class III: No Benefit (Moderate). Benefit = Risk
- Class III: Harm (Strong). Risk > Benefit

Levels of Evidence (LOE):

- Level A: High-quality evidence from more than one RCT, meta-analyses of high-quality RCTs, one or more RCT corroborated by high-quality registry studies.
- Level B-R (Randomized): Moderate-quality evidence from one or more RCTs, meta-analyses of moderate-quality RCTs.
- Level B-NR (Nonrandomized): Moderate-quality evidence from one or more well-designed nonrandomized studies, observational studies, or registry studies, meta-analyses of such studies.
- Level C-LD (Limited data): Randomized or nonrandomized observational or registry studies with limitations of design or execution, meta-analyses of such studies, physiological or mechanistic studies in human subjects.
- Level C-EO (Expert opinion): Consensus of expert opinion based on clinical experience.

Data from Reference 16.

Vasopressin

Vasopressin, also known as antidiuretic hormone, is a potent, nonadrenergic vasoconstrictor that increases blood pressure and systemic vascular resistance. Although it acts on various receptors throughout the body, its vasoconstrictive properties are due primarily to its effects on the V_1 receptor. Measurement of vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC.[50] In one study, plasma vasopressin concentrations were approximately three times as high in survivors compared with nonsurvivors, suggesting that vasopressin is released as an adjunct to epinephrine in life-threatening events such as cardiac arrest.[51]

Vasopressin is proposed to have several advantages over epinephrine. First, the metabolic acidosis that frequently accompanies cardiac arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine. This effect does not occur with vasopressin. Second, the stimulation of beta-receptors caused by epinephrine can increase myocardial oxygen demand and complicate the post-resuscitation phase of CPR. This is not seen with vasopressin use because it does not act on beta-receptors. Vasopressin also may have a beneficial effect on renal blood flow by stimulating V_2 receptors in the kidney, causing vasodilation and increased water reabsorption. With regard to splanchnic blood flow (ie, blood flow to the gastrointestinal tract), however, vasopressin has a detrimental effect when compared to epinephrine.[50] Despite these theoretical advantages with vasopressin, clinical outcomes are not superior to that achieved with epinephrine alone.[52] Furthermore, vasopressin in combination with epinephrine offers no advantage over epinephrine alone.

A multidrug regimen that included vasopressin plus corticosteroid therapy has been evaluated in the setting of in-hospital cardiac arrest.[53–55] The rationale is based on the hemodynamic effects of steroids alone with their potential to impact the intensity of the postresuscitation systemic inflammatory response and organ dysfunction. A recent meta-analysis observed a favorable effect on ROSC and survival to hospital discharge with good neurologic function using this multidrug regimen.[56] The largest randomized controlled trial to evaluate this multidrug approach combined vasopressin (20 units administered after each dose of epinephrine, maximum cumulative dose of 80 units) plus a single dose of methylprednisolone 40 mg.[55] A significant difference in ROSC was detected in the study group but no difference in 30-day survival or survival with favorable neurologic function was detected. Possible reasons for these disparate results could include the lack of corticosteroid use in the postresuscitation phase and the time to trial drug administration, which was longer in this trial.

In summary, vasopressin may be considered in cardiac arrest but offers no benefit when used as a substitute for or in combination with epinephrine compared to the standard dose of epinephrine alone.[16] The combination of methylprednisolone, vasopressin, and epinephrine will require further study before this approach could be routinely recommended.

Antiarrhythmics

Amiodarone or lidocaine are suggested in adults with VF/PVT refractory to defibrillation and epinephrine therapy. The purpose of antiarrhythmic drug therapy following unsuccessful defibrillation and vasopressor administration is to prevent the development or recurrence of VF and PVT. However, clinical evidence demonstrating improved survival to hospital discharge is lacking.[57,58]

A large, randomized, double-blind trial in patients with out-of-hospital cardiac arrest secondary to VF or PVT reported a higher incidence of survival to hospital admission but no difference in survival to hospital discharge.[59] This was the first trial to demonstrate the benefit of any antiarrhythmic agent over placebo in patients with out-of-hospital cardiac arrest. A subsequent trial compared amiodarone with lidocaine in patients with out-of-hospital cardiac arrest due to VF.[60] In this trial, amiodarone was associated with improved survival to hospital admission compared with lidocaine but there was no difference in survival to hospital discharge. A most recent trial compared amiodarone and lidocaine to placebo in patients with an out-of-hospital arrest with shock-resistant VF/PVT.[61] Both agents were associated with an increase in survival to hospital admission compared to placebo. However, no significant difference in survival to hospital discharge was observed for amiodarone versus placebo, lidocaine versus placebo, or amiodarone versus lidocaine. A subgroup analysis noted higher rates of survival to hospital discharge with both agents (versus placebo) in patients with bystander-witnessed cardiac arrest.

Magnesium

Severe hypomagnesemia has been associated with VF/PVT, but the routine administration of magnesium during a cardiac arrest has not demonstrated any benefit in clinical outcomes. Two observation trials noted an improvement in ROSC in patients with arrests associated with torsades de pointes.[16] Therefore, magnesium should only be administered in the setting of torsades de pointes.

Thrombolytics

Since most cardiac arrests are related to either myocardial infarction or pulmonary embolism (PE), several investigators have evaluated the role of thrombolytics during CPR. Initial studies evaluating the use of thrombolytics in cardiac arrest yielded mixed results. The most rigorous study performed to date randomized patients with out-of-hospital cardiac arrest to receive either tenecteplase or placebo.[62] Both ROSC and survival to hospital discharge were similar between groups, criteria for futility were met, and the trial was terminated. The incidence of intracranial hemorrhage was significantly greater with tenecteplase versus placebo (2.7% vs 0.4%). Given these results, fibrinolytic therapy should not be used routinely in cardiac arrest. When PE is suspected, its use may be warranted.[16]

Pulseless Electrical Activity and Asystole

Nonpharmacologic Therapy

④ Pulseless electrical activity is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. Patients with PEA have mechanical cardiac contractions but they are too weak to produce a palpable pulse or blood pressure. Although PEA is classified as a "rhythm of survival," the likelihood of successful resuscitation is much lower than seen with VF/PVT.[1] PEA is often caused by a treatable underlying cause, and the resuscitation team must quickly identify and correct it if the resuscitation is to be successful (Table 41-2). Asystole occurs when there is a lack of electrical activity in the heart and appears as a flat line on the ECG. Asystole is often not amenable to treatment. Like PEA, successful treatment of asystole depends almost entirely on diagnosing the underlying cause.

TABLE 41-2

Underlying Causes of Pulseless Electrical Activity and Asystole

Condition	Clues	Treatment
Hypovolemia	History, flat neck veins	Intravenous fluids
Hypoxia	Cyanosis, blood gases, airway problems	Ventilation, oxygen
Hydrogen ion (acidosis)	History of bicarbonate-responsive preexisting acidosis	Sodium bicarbonate, hyperventilation
Hyper (Hypo) kalemia	History of renal failure, diabetes, recent dialysis, dialysis fistulas, medications	Calcium chloride, insulin, glucose, sodium bicarbonate, sodium polystyrene sulfonate, dialysis
Hypothermia	History of exposure to cold, central body temperature	Rewarming, oxygen, intravenous fluids
Hypoglycemia	History of diabetes	Glucose infusion
Toxin (Drug overdose)	Bradycardia, history of ingestion, empty bottles at the scene, pupils, neurologic exam	Drug screens, intubation, lavage, activated charcoal
Tamponade (Cardiac)	History (trauma, renal failure, thoracic malignancy), no pulse with CPR, vein distention, impending tamponade-tachycardia, hypotension, low pulse pressure changing to sudden bradycardia as terminal event	Pericardiocentesis
Tension pneumothorax	History (asthma, ventilator, chronic obstructive pulmonary disease, trauma), no pulse with CPR, neck vein distention, tracheal deviation	Needle decompression
Thrombosis, coronary	History, ECG, enzymes	PCI, thrombolytics, oxygen, nitroglycerin, heparin, aspirin, morphine
Thrombosis, pulmonary	History, no pulse with CPR, distended neck veins	Pulmonary arteriogram, surgical embolectomy, thrombolytics
Trauma	History, examination	Volume infusion, intracranial pressure monitoring, bleeding control, surgical intervention

Data from Reference 16.

The algorithm for treating PEA and asystole is the same. Both conditions require CPR, airway control, and IV access. Asystole should be reconfirmed by checking a second lead on the cardiac monitor. Defibrillation should be avoided because the parasympathetic discharge that occurs with defibrillation may reduce the chance of ROSC and worsen the chance of survival. High-quality CPR without interruption remains an emphasis along with identifying a correctable cause.

Pharmacologic Therapy

The primary pharmacologic agent used in the treatment of asystole or PEA is epinephrine. In a systematic review of randomized controlled trials evaluating epinephrine in out-of-hospital cardiac arrest due to nonshockable rhythms, significant improvements were observed in ROSC, survival to hospital admission, and 3-month survival.[33] Survival with good neurologic function at 3-months improved, albeit not statically significant. Nevertheless, the global benefits of epinephrine were most apparent in patients with nonshockable versus shockable rhythms.

Similar to shockable rhythms, the time to epinephrine administration is an important confounder related to its efficacy. One large study of patients with out-of-hospital cardiac arrest from nonshockable rhythms reported a 4% decrease in the odds of survival to hospital discharge with each minute delay in epinephrine administration.[63] Furthermore, the odds of surviving with good neurologic function decreased by 6% with each minute delay. Other observational studies have yielded similar results. In a large North American registry trial, survival to hospital discharge was highest when epinephrine was administered within 5 minutes after EMS arrival and decreased with each 5-minute period thereafter.[37] A study from a Japanese database revealed worse neurological outcomes when the time to epinephrine administration exceeded 10 minutes.[64] Early epinephrine administration is also important after in-hospital cardiac arrests with nonshockable rhythms. In one large study using the Get With The Guidelines-Resuscitation database, a step-wise decrease in survival was observed with each incremental delay in epinephrine administration.[39] Thus, epinephrine should be administered as soon as possible.

Acid/Base Management

Acidosis seen during cardiac arrest results from decreased blood flow and inadequate ventilation. Chest compressions generate only approximately 25% of normal cardiac output, leading to inadequate organ perfusion, tissue hypoxia, and metabolic acidosis. In addition, the lack of ventilation causes retention of carbon dioxide, leading to respiratory acidosis. Acidosis produces not only reduced myocardial contractility but also lowers the fibrillation threshold. Despite the deleterious effects of acidosis on normal physiology, sodium bicarbonate has not been shown to improve ROSC or survival to hospital discharge.[65] One large observational study reported sodium bicarbonate use was associated with a lower probability of both ROSC and a favorable neurologic outcome.[66] In addition, this negative association persisted in the subgroup of patients having arrests of long duration (defined as >22.6 minutes of resuscitation) conflicting with some beliefs that sodium bicarbonate may be useful in this setting.

Sodium bicarbonate may have detrimental effects because of the following reaction: $[HCO_3^-] + [H^+] \leftrightarrow [H_2O] + [CO_2]$.[67] When sodium bicarbonate is added to an acidic environment, the reaction will shift to the right, thereby increasing tissue and venous hypercarbia. The carbon dioxide generated by this reaction will diffuse into the cell and decrease intracellular pH. The accumulation of intracellular carbon dioxide, specifically within the myocardium, is inversely correlated with CPP produced by CPR. Intracellular acidosis also will decrease myocardial contractility, further complicating the low-flow state associated with CPR. Furthermore, treatment with sodium bicarbonate often overcorrects extracellular pH because sodium bicarbonate has a greater effect when the pH is closer to normal. The induced alkalosis causes an increase in the affinity of oxygen to hemoglobin ("left shift"), thus interfering with oxygen release into the tissues.

Sodium bicarbonate is not recommended for routine use in patients with cardiac arrest.[16] It can be considered in special circumstances such as patients with hyperkalemia, tricyclic antidepressant overdose, or salicylate toxicity.

Postresuscitative Care

⑤ Following the ROSC from a cardiac arrest, patient management should be directed toward the postcardiac arrest syndrome.[68] There are four main components of the postcardiac arrest syndrome which highlight succinct pathophysiologic processes and potential areas for treatment: hypoxic brain injury, myocardial dysfunction, systemic ischemia-reperfusion response, and the underlying precipitating pathology (Table 41-3).[69] Many of the concepts within these four components surround the principles of basic ICU care (eg, adequate oxygenation, circulatory support, hemodynamic optimization, and prevention of secondary brain injury). Similar to other ICU patients, a systems-based approach should be used to assess the role of drug therapy. Key components of pharmacotherapy related to postcardiac arrest care are described below.

TABLE 41-3

Postcardiac Arrest Syndrome

Syndrome	Pathophysiology	Clinical Manifestation
Hypoxic brain injury	• Impaired cerebrovascular autoregulation • Cerebral edema • Postischemic neurodegeneration	• Seizures • Coma • Myoclonus • Cognitive dysfunction • Cortical/Spinal Stroke • Brain death
Myocardial dysfunction	• Global hypokinesis • Acute coronary syndrome	• Reduced cardiac output • Cardiogenic shock • Dysrhythmias
Systemic ischemia-reperfusion response	• Systemic inflammatory response syndrome • Impaired vasoregulation • Hypercoagulability • Microcirculatory dysfunction • Adrenal suppression • Immunosuppression	• Tissue hypoxia • Hypotension • Fever • Hyperglycemia • Infection • Multi-system organ failure
Underlying precipitating pathology	• Cardiovascular disease • Pulmonary disease • Hypovolemia/Hemorrhage • Stroke • Pulmonary embolism • Poisoning/overdose • Infection • Electrolyte disturbances	• Clinical manifestation will be specific to the underlying cause

Data from Reference 69.

Neurologic Management and Prevention of Secondary Brain Injury

Following the restoration of blood flow after a cardiac arrest, there is a sequence of chemical cascades and destructive enzymatic reactions that result in edema, cerebral hypoxia, and neuronal injury. These reactions include free-radical production, excitatory amino acid release, and calcium shifts, which lead to mitochondrial damage and apoptosis (programmed cell death).[70] In addition, seizures, hyperglycemia, and hyperthermia can increase metabolic demand and further contribute to secondary hypoxic brain injury. The severity of hypoxic brain injury is a key determinant for survival; thus, appropriate preventative or treatment strategies are crucial.

Targeted Temperature Management

Targeted temperature management (TTM) has been a cornerstone of post-resuscitation care for the last 20 years. TTM can protect against cerebral injury by suppressing the chemical reactions associated with cerebral injury. Additionally, TTM can decrease cerebral metabolism and oxygen consumption. For each 1°C drop in temperature, cerebral metabolism decreases by 6% to 10%.[70]

Early success with TTM was described in two pivotal trials.[71,72] In the first trial, patients who had been resuscitated after cardiac arrest due to VF but remained comatose were assigned randomly to undergo TTM through therapeutic hypothermia, targeting a temperature of 32°C to 34°C (89.6°F to 93.2°F), for 24 hours.[71] More patients in the hypothermia group achieved a favorable neurologic outcome compared to the normothermia group. The second study targeted 33°C (91.4°F) maintained for 12 hours.[72] Likewise, more patients in the hypothermia group had good neurologic function at the time of hospital discharge (to either home or a rehabilitation facility) compared to patients in the normothermia group.

Since the publication of these landmark articles, several randomized controlled trials evaluating TTM have produced mixed results. One randomized controlled trial compared TTM delivered at 33°C versus 36°C (91.4°F vs 96.8°F) for 36 hours to assess whether the benefits of TTM were related to hypothermia or prevention of hyperthermia, which occurred periodically in a previous trial.[73] Overall, this study reported no significant differences in all-cause mortality, end-of-trial mortality, or poor neurologic function. A second randomized controlled trial evaluated the impact of prehospital cooling on survival.[74] Although the target temperature (less than 34°C [89.6°F]) was reached approximately 1 hour sooner in the intervention group compared to controls, prehospital cooling was not associated with increased survival to hospital discharge or improvement in neurological status. Another study found that the duration of TTM (24 hours compared to 48 hours) had no impact on neurologic outcomes assessed at 6 months.[75] In one trial, patients with nonshockable rhythms who achieved ROSC and who were randomized to TTM targeting hypothermia (33°C [91.4°F]) had improved survival with a favorable neurologic outcome at day 90 compared to those who received normothermia (37°C [98.6°F]).[76] The most recent trial (TTM-2 trial) compared hypothermia (33°C [91.4°F]) versus normothermia (37°C [98.6°F]) in patients with both shockable and nonshockable rhythms and found no significant differences in 6-month mortality or poor functional outcome.[77] Similarly, there were no differences based on the initial rhythm being shockable or nonshockable. A subsequent systematic review evaluated the impact of TTM at 32-34°C (89.6-93.2°F) versus normothermia and found no differences in hospital survival, survival to 90 or 180 days, and survival with good neurologic outcome.[78]

One potential reason for these discordant results could be the influence of initial illness severity assessed immediately post-ROSC. One study evaluated survival to hospital discharge in patients who received TTM at 33°C or 36°C (91.4°F or 96.8°F), stratified by illness severity using the Pittsburgh Cardiac Arrest Category (PCAC) score.[79] There was a robust interaction between PCAC score and the effect of TTM at 33°C (91.4°F) whereby a greater benefit was observed in patients with higher severity of illness. In contrast, in patients with lower severity of illness, 36°C (96.8°F) was associated with higher survival rates. Further prospective research will have to validate these findings.

Current guidelines (published before the TTM-2 trial data were available) recommend TTM between 32 and 36°C (89.6°F and 96.8°F) for at least 24 hours.[16] Following the TTM period, fever should be prevented. However, a draft of the Consensus on Science with Treatment Recommendations (CoSTR) for TTM suggests preventing fever by targeting a temperature less than 37.5°C (99.5°F), acknowledging that the benefit of targeting hypothermia (32-34°C [89.6-93.2°F]) in subpopulations surviving cardiac arrest is unknown.[80]

Inducing hypothermia is not without risk. Shivering occurs during the induction phase, increasing metabolic rate and myocardial oxygen demand. Several strategies exist to blunt the thermoregulatory response to hypothermia, and these measures should be implemented accordingly.[81] These measures include acetaminophen, buspirone, magnesium, meperidine, sedation with dexmedetomidine or propofol, and analgesia with fentanyl. In some cases, neuromuscular blocking agents (NMBA) may be required. Neuromuscular blockade, however, may mask the appearance of seizures which are common postcardiac arrest. One randomized study showed no difference in serum lactate levels, survival, or neurologic function with continuous NMBA.[82] In contrast, a large observational study found that as-needed NMBA increased the odds of good outcomes compared to escalating sedation doses without NMBA.[83] When a NMBA is required, as-needed, intermittent dosing regimens are preferred over continuous infusions.

Hypothermia can also affect drug metabolism and clearance resulting in supratherapeutic concentrations.[84] These alterations may persist even upon rewarming into the posttreatment period. This is particularly relevant for sedatives and analgesics, which could confound prognostication. In fact, midazolam clearance is estimated to decrease by up to 11% for each degree Celsius.[84] Propofol clearance is 23% lower in hypothermic compared to normothermic patients. A 45% decrease in clearance has been noted with fentanyl. Careful dose titration should occur to minimize drug accumulation induced by TTM.

Other potential complications described with TTM include coagulopathy, dysrhythmias, bradycardia, diuresis, electrolyte disorders, hyperglycemia, and infections.[81] An intracellular shift of electrolytes like potassium can occur with hypothermia therefore frequent assessment and supplementation are required. Aggressive repletion, however, should be avoided because hyperkalemia may occur during rewarming as sequestered potassium is released from the intracellular compartment.

Seizures

Seizures postcardiac arrest are an indicator of severe brain injury and are associated with poor prognosis. The incidence of seizures is approximately 10% to 30%.[85,86] Seizures usually occur within 8 to 24 hours postarrest but can occur later, especially after rewarming in patients treated with TTM. Continuous electroencephalogram monitoring for at least 72 hours is suggested. Either valproic acid or levetiracetam should be used as first-line therapy for the treatment of seizures. Medications for prophylaxis of seizures are not indicated.

Respiratory Management

After ROSC, it is imperative to ensure a secure airway is in place (ie, an endotracheal tube) and oxygenation is appropriate. Rearrest is common in the first minutes after resuscitation (occurring in roughly one of five cases). Hypoxia and hypotension are also frequently seen.[81] Both hypoxia and hyperoxia are associated with adverse outcomes after cardiac arrest and should be avoided.[81] Initially, 100% oxygen should be used during the resuscitation effort. If ROSC is obtained, the fraction of inspired oxygen can be titrated down as tolerated to maintain an oxygen saturation of 92-98% (0.92-0.98).[16] Overventilation, which leads to hypocapnia, should be avoided since hypocapnia causes vasoconstriction and may lead to cerebral ischemia.

Cardiovascular and Hemodynamic Management

Given that cardiac ischemia is the most common cause of cardiac arrest, a rapid search for ECG changes consistent with acute myocardial infarction should be undertaken immediately.[81] If an acute myocardial infarction is present, urgent revascularization should be performed.

Shock will be present in 50% to 70% of patients post-ROSC.[87] Cardiac echocardiography should be performed to evaluate myocardial dysfunction and can guide pharmacotherapy decisions. Volume management should be individualized for each patient based on underlying organ dysfunction, the hemodynamic target chosen, and the etiology of the arrest. Inotropes and vasopressors should be used accordingly. Steroids should not be routinely given but can be considered in refractory cases or when adrenal insufficiency is evident.

The choice for a target blood pressure is a balance between overall heart function (eg, presence of left ventricular dysfunction) and the need to maintain adequate cerebral perfusion. This is complicated by the fact that following ROSC, cerebral hypoperfusion is common, lasting several hours to days after resuscitation. During this time, cerebral vascular resistance is increased and autoregulation is impaired. Autoregulation is the ability of the cerebral vasculature to regulate constant blood flow to the brain across a range of systemic blood pressures. In the post-resuscitation phase, increased systemic pressures are needed to maintain adequate blood flow to the brain. While an optimal goal of mean arterial pressure (MAP) target has not been determined, augmenting blood pressure to achieve a goal of MAP of more than 80 mm Hg has been recommended, especially when advanced cerebral monitoring is not in use.[81]

Glucose Management

Both hyperglycemia and hypoglycemia are associated with poor outcomes in critically ill patients. Hyperglycemia is particularly common postcardiac arrest and can be influenced by TTM.[88] During therapeutic hypothermia, insulin sensitivity is significantly lower and highly variable. Upon rewarming, insulin sensitivity increases which could increase the risk for hypoglycemia. One small study compared strict (72 – 108 mg/dL [4 - 6 mmol/L]) with moderate (108 – 144 mg/dL [6 - 8 mmol/L]) glycemic control in patients with ROSC after out-of-hospital cardiac arrest.[89] There was no survival benefit recognized with strict glucose control but hypoglycemic events were higher. Maintaining glucose between 81 and 180 mg/dL (4.5 and 10 mmol/L)after cardiac arrest is suggested.

Infectious Disease Management

Therapeutic hypothermia is associated with an increased risk for infectious complications, particularly ventilator-associated pneumonia. A large trial evaluated the benefit of a short course (48 hours) of antibiotic therapy (amoxicillin-clavulanate) in patients who received TTM at 32-34°C (89.6-93.2°F).[90] Patients who received antibiotic prophylaxis had a lower incidence of early-onset pneumonia but no differences were observed in the incidence of late-onset pneumonia, number of ventilator-free days, ICU length of stay, or mortality. Routine use of antibiotic prophylaxis, therefore, is not recommended.[18]

Special Populations

Asthma

Asthma is a common disorder, and despite modern therapies, there are still in excess of 3,500 asthma-related deaths annually in the United States.[16] True cardiac arrest in asthma is infrequent, as the primary pathophysiology is respiratory compromise and poor ventilation.[91] Asthma exacerbations are a combination of bronchoconstriction, airway inflammation, and mucous plugging. This leads to severe air trapping, hyperinflation, and hemodynamic compromise. While wheezing is common in an asthma exacerbation, it does not correlate with the degree of airway obstruction. In contrast, with worsening disease (and subsequent decrease in airflow), wheezing may disappear. Further, several disease states cause wheezing, including pulmonary edema, pneumonia, anaphylaxis, foreign bodies, and tumors.

Patients with life-threatening asthma need to be treated aggressively with bronchodilators and corticosteroids. Adjunctive therapies include anticholinergics, magnesium sulfate, ketamine, helium/oxygen mixtures, or inhaled anesthetics.[92–96] Noninvasive ventilation can be attempted if the patient is deteriorating and still awake. This may prevent the need for mechanical ventilation.[97] The decision to intubate is a clinical judgment. However, the endotracheal tube will not solve the airway problem and aggressive asthma management needs to continue after intubation. In addition, intubation and positive airway pressure can trigger further bronchoconstriction or hemodynamic compromise.

The provision of BLS and standard ACLS measures should be followed in patients with acute asthma.[16] However, since the effect of auto-positive end-expiratory pressure, known as breath stacking, can be severe, a strategy of low respiratory rate and volume ventilation may be appropriate.[16] Similarly, for cardiac arrest in patients with acute asthma, especially when ventilation is difficult, tension pneumothorax should be strongly considered.[16]

Anaphylaxis

Anaphylaxis is a severe allergic reaction that can lead to airway obstruction and cardiovascular collapse. In the United States, at least 1.6% of adults have experienced anaphylaxis with about 200 individuals dying each year.[16] The initial signs can be nonspecific, but a “sense of impending doom” is common. Rhinitis often leads to laryngeal edema with stridor in the upper airway. Bronchoconstriction often mimics an acute asthma attack.

Cardiovascular collapse is common in severe anaphylaxis due to vasodilation and increased capillary permeability. This can rapidly lead to myocardial hypoperfusion and ischemia and to full cardiac arrest. There are no randomized trials comparing strategies to manage arrest due to anaphylaxis.[16] Therefore, standard basic and advanced life support measures should be followed.

Clinicians are advised to stop any drug or remove any trigger (eg, stinger after a bee sting) suspected of causing anaphylaxis. Early advanced airway management is recommended due to the potential for rapidly developing laryngeal edema. Epinephrine remains the cornerstone of the treatment.[16] The recommended dose is 0.2 to 0.5 mg and should be administered via intramuscular injection to all patients with signs of systemic allergy.[16] This can be repeated every 5 to 15 minutes if there is no clinical improvement. About 10% of patients will require more than one dose and 98% will respond with two or three doses.[98] Fluid resuscitation is usually required for restoration of circulation and is supported by one study in which the combination of fluid resuscitation and epinephrine was effective in treating hypotension unresponsive to vasoactive drugs.[99] Other agents such as antihistamines, inhaled beta-agonists, and IV corticosteroids have been used successfully in anaphylaxis and may be considered in cardiac arrest due to anaphylaxis but there are no data illustrating their benefit.[16]

Opioid Overdose

Opioid-associated cardiac arrests are responsible for approximately 115 deaths per day in the United States, largely affecting individuals aged 25 to 65 years.[16] Opioid overdose is characterized by central nervous system and respiratory depression that ultimately progresses to respiratory arrest and then cardiac arrest. Maintaining an airway and ventilation are, therefore, the highest priorities. Naloxone is an effective antidote to reverse the effect of opioids, but there are no studies demonstrating improvements in outcomes during cardiac arrest.[16] Naloxone should be administered along with standard basic and advanced life support measures but should not delay components of high-quality CPR. Repeat doses may be necessary with ingestion of long-acting or sustained release opioids. Naloxone is ineffective for arrests caused by nonopioids or other overdose scenarios.

Pregnancy

Pregnancy is a unique situation where the survival of both the fetus and the mother depends on CPR. Despite the fact that pregnant patients are younger than most cardiac arrest victims, the incidence of cardiac arrest during pregnancy appears to be on the rise in the United States.[16] Historically, survival has been poor but survival rates of nearly 60% have been reported.[100] Survival is largely dependent on the underlying etiology. The most common causes of cardiac arrest during pregnancy are anesthetic complications, accidents, bleeding, cardiovascular, drugs, embolism, fever, and hypertension.[101]

The best hope for survival of the fetus is maternal survival. Fetal monitoring is not advised during cardiac arrest because of potential interference with maternal resuscitation. High-quality chest compressions are essential and hand placement is similar to a nonpregnant patient. Because the vena cava and aorta can be obstructed by the uterus in the second and third trimesters during pregnancy, CPR procedures should be modified. Manual lateral uterine displacement (ie, pulling the uterus to the side) is recommended.[16] Alternatively, tilting the patient laterally by approximately 30 degrees can be used but the quality of chest compressions is compromised.

Pregnant patients are more prone to hypoxia; thus, oxygenation and airway management are important. The airway may be smaller because of the hormonal changes and edema.[101] Similarly, because of increased intra-abdominal pressure exerted by the uterus, as well as hormonal changes that change the resting state of the gastroesophageal sphincter, there is an increased risk of aspiration. The rescuer may need to give smaller respiration volumes than normal.

The ACLS provider should follow the standard guidelines for the pregnant patient, including the same use of chest compressions, defibrillation, and medications.[101] Epinephrine remains the vasopressor of first choice despite concerns that it can diminish uterine blood flow. Antiarrhythmics should be considered for refractory, shock-resistant VF/PVT. No medication should be withheld in the setting of cardiac arrest because of concerns about fetal teratogenicity. While there are clear changes in pharmacokinetic parameters (ie, the volume of distribution and clearance) during pregnancy, there are limited data to justify alternative dosing strategies. Standard doses, therefore, are recommended.

Although the etiology of arrest in pregnancy is often the same as in the nonpregnant patient, there are several unique causes that need to be considered.[101] Excess magnesium sulfate administration (ie, iatrogenic from treating eclampsia) can prompt cardiac arrest. In such cases, the therapeutic administration of calcium can be lifesaving. An amniotic embolism can lead to complete cardiovascular collapse during labor and delivery. Pre-eclampsia/eclampsia developing after the 20th week of gestation can produce hypertension and multiple organ dysfunction, including cardiac arrest. Vascular events including acute coronary syndromes and acute PE can also be a cause.

It is paramount to remember that unless circulation is restored to the mother, both the mother and the fetus will succumb. The resuscitation leader should consider the need for emergent cesarean delivery if ROSC is not obtained within 5 minutes.[16] In patients who achieve ROSC but remain comatose, TTM with fetal monitoring is recommended.

Accidental Hypothermia

Accidental (unintentional) hypothermia (not therapeutic hypothermia used postarrest) occurs when the body temperature is less than 30°C (86°F). It is associated with marked derangements in body function. Because it can depress virtually every body system, including pulse and respiration, the patient may appear to be dead. If the patient still has a perfusing rhythm, therapy is directed toward rewarming techniques. For mild hypothermia (ie, >34°C [93.2°F]), passive rewarming is recommended.[102] For moderate hypothermia (ie, 30°C–34°C [86°F–93.2°F]), active external rewarming is recommended, and for severe hypothermia (ie, <30°C [86°F]), active internal rewarming is recommended. Patients need to be manipulated very gently as VF is sometimes precipitated by movement.

If the patient is in cardiac arrest, then the standard BLS algorithm should be followed. Pulse and respiratory rates may be slow or difficult to detect and ECG may show asystole. If the victim displays no signs of life, then chest compressions and rescue breaths should ensue immediately. If the patient is in VF or PVT, electrical therapy should be given in a standard manner and CPR should immediately resume. Source of heat loss should be minimized (ie, removal of wet clothing, protection from the environment). The role for medications is unclear. Some resources recommended withholding epinephrine when the body temperature is less than 30°C (86°F). Current recommendations state it is reasonable to administer epinephrine according to standard ACLS practices.[16]

It is debatable when to stop resuscitative efforts in hypothermic patients. Many authors have proposed that a patient should not be pronounced dead until the core temperature has been restored to near normal.[102]

Trauma

Cardiac resuscitation of the trauma arrest patient should follow standard BLS and ACLS practices. Survival rates following an out-of-hospital cardiac arrest due to trauma are low.[98] Survival is higher in young patients with treatable penetrating injuries. Common reversible causes of traumatic cardiac arrest are hemorrhage, tension pneumothorax, asphyxia, and pericardial tamponade.

Trauma patients often suffer head or cervical injuries; thus, cervical spine precautions should be used. A jaw thrust maneuver is the preferred way to open the airway, with in-line stabilization during attempts at advanced airway placement.[16] Inadequate ventilation of one side is usually due to tube malposition, tension pneumothorax, or hemothorax. These conditions are usually treated by medical personnel at the hospital after transport.

Chest compressions should be performed in a standard manner. Chest compressions are less likely to be effective when cardiac arrest is due to hypovolemia, cardiac tamponade, or tension pneumothorax. Treatment for these “reversible causes” should be prioritized.

Ongoing hemorrhage must be controlled with either temporizing or definitive measures. Restoration of blood volume with blood products is essential as resuscitation is unlikely if the patient has severe hypovolemia. Tranexamic acid can be considered for patients with traumatic hemorrhage who present within 3 hours from injury.[103] Resuscitative endovascular balloon occlusion of the aorta is being evaluated in both traumatic and nontraumatic cardiac arrest to improve the effectiveness of chest compressions. Available data suggest this technique may be beneficial.[104]

Open thoracotomy for trauma-induced arrest may be indicated for select patients.[105] Open thoracotomy can allow relief of tamponade, control of major vessel hemorrhage, or direct repair. Open thoracotomy is a strong recommendation for patients who are pulseless but have signs of life after penetrating thoracic injury.[105] In the setting of penetrating extra-thoracic injury or blunt injury, open thoracotomy is a conditional recommendation.

A unique cause of cardiac arrest caused by a blow to the anterior chest or sternum during the repolarization part of the cardiac cycle is called “Commotio Cordis.”[106] These events are commonly seen in young athletes and can be caused by a fall or a baseball or hockey puck striking the sternum. Prompt recognition and rapid defibrillation are often lifesaving. Provision of BLS, the use of an AED, and standard ACLS procedures are appropriate for this type of arrest.

Drowning

Drowning is the result of primary respiratory impairment following immersion/submersion in a liquid. It is a common, preventable cause of morbidity and mortality. Cardiac arrest in this setting is due to hypoxia. The most powerful predictor of outcome, therefore, is the duration of submersion. In one study, the probability of a good outcome was only 2% when the submersion duration exceeded 10 minutes.[107] With submersion durations that exceed 25 minutes, resuscitation efforts may be futile.

Because hypoxia is the underlying etiology of cardiac arrest in drowning victims, the traditional A-B-C approach should be used instead of C-A-B.[102] Early care consists of immediate rescue breathing, even before they are removed from the water. Once the victim is removed from the water, immediate chest compressions should be started if they are pulseless. Drowning victims can present with any of the pulseless rhythms; standard guidelines for these rhythms should be followed. A “Drowning Chain of Survival” has been proposed to improve outcomes.[108] The five links in the chain are as follows: prevent drowning, recognize distress, provide flotation, remove from water, and provide care as needed.

Electrocution/Lightning

There are many etiologies of electrical shock injuries including a lightning strike, high-tension current, or household current. The severity of injury depends on the site, type of current, duration of contact, pathway, and the magnitude of delivered electricity.

Cardiac arrest is common in electrical injury due to the current passing through the heart during the "vulnerable period" of the cardiac cycle. In large-current events, such as lightning strikes, the heart undergoes massive depolarization. In some cases, the intrinsic pacemaker can restore an organized cardiac electrical cycle. Injury to other muscles, however, particularly the thoracic musculature, and suppression of the respiratory center can lead to inadequate ventilation, hypoxia, and subsequent cardiac arrest. Ventilatory support, therefore, must be maintained after ROSC is achieved.

When approaching a victim of electrocution, the rescuer must first be certain of his or her own safety. Prompt CPR and ACLS, when available, is indicated. Electric shock is often associated with multiple trauma, including spinal injury, multiple injuries to the skeletal muscles, as well as fractures. These factors need to be evaluated by the resuscitation team.

Airway control may be difficult due to the edema that often accompanies electrical injuries; thus, an advanced airway early in the treatment process is recommended.[102] With soft tissue swelling, there is often a need for aggressive fluid resuscitation in these patients. The underlying tissue, or visceral organ damage, is often worse than the external appearance. It is usually recommended that these patients can be transferred to centers with expertise in dealing with these types of injuries.

Drug Administration

The routes of administration available for drug delivery during CPR include IV (both central and peripheral access), IO, and endotracheal. Each route represents a compromise between access and efficacy in introducing the drug into the central circulation. When selecting a route for drug administration, it is important to minimize any interruptions in chest compressions during CPR.

The traditional access site for parenteral medication administration during a cardiac arrest is a peripheral IV line. Peripheral drug administration yields a peak concentration in the major systemic arteries in roughly 1.5 to 3 minutes but this time can be shortened by up to 40% if the drug is followed by a 20-mL fluid bolus and elevating the extremity.[109] Central venous access will result in a faster and higher peak drug concentration than peripheral access but central line access is not needed in most resuscitation attempts. If a central line is already present, it should be the access site of choice. An appropriately trained provider may consider placing a central line if one is not present and attempts to establish IV or IO access are unsuccessful, but CPR should not be interrupted. Central lines located above the diaphragm are preferable to those located below the diaphragm because of poor blood flow during CPR.

⑥If IV access cannot be obtained, IO is the next preferred route for drug and fluid administration.[16] Several IO access devices are commercially available that allow for rapid insertion and are easy to use. Pharmacokinetic data have demonstrated similar areas under the curve and times to peak concentration for sternal IO and central IV administration.[110] Clinical data, however, have suggested outcomes may be worse with IO administration versus IV.[18] IO administration should only be used if initial attempts at IV access are unsuccessful. Potential anatomic sites for insertion of an IO needle are the sternum, tibia, and humerus.[110] The need for cessation of chest compressions, however, along with the risk of injury to the heart or great vessels makes the sternum a less desirable site for insertion. As such, the proximal tibia is typically preferred because it is easy to locate, provides a flat, wide surface for insertion, has minimal subcutaneous layers overlying the bone, and does not interfere with CPR.

If neither IV nor IO access can be established, a few drugs can be administered through an endotracheal tube. These drugs are atropine, lidocaine, epinephrine, naloxone, and vasopressin.[109] There are no data with amiodarone. Medications administered through the endotracheal route will have both a lower and delayed peak concentration than when drugs are administered by the IV or IO routes. In one clinical trial, lower rates of ROSC, hospital admission, and hospital discharge were observed with endotracheal drug administration compared to IV.[109] If the endotracheal route is to be used, the recommended medication dose is 2 to 2.5 times larger than the IV/IO dose. Providers should dilute the medication in 5 to 10 mL of either sterile water or normal saline. Better drug absorption may be achieved with sterile water.[109]

EVALUATION OF THERAPEUTIC OUTCOMES

The optimal outcome following CPR is an awake, responsive, spontaneously breathing patient. Patients must remain neurologically intact with minimal morbidity following the resuscitation if it is to be considered a success.

Monitoring during cardiac arrest includes both CPR performance and physiologic. CPR performance can be assessed using devices that provide real-time feedback on CPR quality. In many cases, rhythm assessment via ECG and pulse checks are the only physiologic parameters available to guide therapy. Palpating a pulse to determine the efficacy of blood flow during CPR, however, has not been shown to be useful. Invasive hemodynamic monitoring (eg, CPP, central venous oxygenation) can provide useful information during CPR but these are seldom available. Arterial diastolic pressure may be a reasonable surrogate for CPP; values less than 20 mm Hg are generally considered suboptimal, and a goal of more than 25 mm Hg is suggested.[111] An arterial central venous oxygen saturation of less than 30% (0.30) is indicative of poor CPR quality.[109]

$ETCO_2$ monitoring is a useful method to assess cardiac output during CPR and has been associated with ROSC. The main determinant of carbon dioxide excretion is the rate of delivery from the peripheral tissues to the lungs. Increasing cardiac output through effective CPR will yield higher $ETCO_2$ levels. Therefore, $ETCO_2$ levels reflect the cardiac output generated by CPR. Persistently low $ETCO_2$ values (<10 mm Hg [1.3 kPa]) during CPR in intubated patients suggest ROSC is unlikely.[16] $ETCO_2$ levels that exceed 20 mm Hg (2.7 kPa) may be associated with a higher chance for ROSC.[18]

Evaluation of outcomes in the post-resuscitation phase should be directed toward the components of the postcardiac arrest syndrome. Because the postcardiac arrest syndrome can affect practically every organ system, a review-of-systems approach for assessment (ie, “head-to-toe”) is strongly suggested. Neuroprognostication should occur at least 5 days after ROSC (or 72 hours after normothermia) for patients who receive TTM because of the prolonged effects of sedatives noted with hypothermia.

The latest link added to the “chain of survival” is recovery. Many patients who survive cardiac arrest suffer from prolonged emotional, cognitive, physical, and neurologic symptoms. In fact, one-third of survivors experience symptoms of anxiety, depression, and posttraumatic stress disorder.[16] Family members and caregivers may also experience stress during the recovery period. A multimodal plan should be provided at hospital discharge that includes instructions for treatment, rehabilitation, and surveillance. In addition, both short-term and long-term expectations should be clearly defined with appropriate action plans for each phase of the recovery.

CONCLUSION

Cardiac arrest is often fatal, but rapid recognition and treatment can result in a favorable outcome. The “Chains of Survival” as described by the AHA provides a framework for treatment. Early recognition and response including high-quality chest compressions with minimal interruptions, early defibrillation, and post-resuscitation care remain major hallmarks of therapy. Nevertheless, there are many areas of uncertainty including the optimal approach for oxygenation and ventilation, the role of drug therapy (eg, epinephrine), the value of TTM, resuscitation targets, and the role of extracorporeal therapies (ie, cardiopulmonary bypass), and the value of neuroprotective agents.[112] A comprehensive research approach, consisting of randomized controlled trials, registry-based studies, pragmatic trials, and animal/laboratory research will be necessary to advance our understanding and improve outcomes.

ABBREVIATIONS

ACLS	advanced cardiac life support
AED	automated external defibrillator
AHA	American Heart Association
BLS	basic life support
CI	confidence interval
CPP	coronary perfusion pressure
CPR	cardiopulmonary resuscitation
ECC	emergency cardiovascular care
ECG	electrocardiogram
EMS	emergency medical services
ETCO$_2$	end-tidal carbon dioxide
IO	intraosseous
IV	intravenous
MAP	mean arterial pressure
OR	odds ratio
PCI	percutaneous coronary intervention
PEA	pulseless electrical activity
PE	pulmonary embolism
ROSC	return of spontaneous circulation
PVT	pulseless ventricular tachycardia
SBP	systolic blood pressure
VF	ventricular fibrillation

SELF-ASSESSMENT QUESTIONS

1. Which rhythm is associated with the worst prognosis when noted as the first identifiable rhythm following a cardiac arrest?

   A. Asystole

   B. Pulseless electrical activity

   C. Pulseless ventricular tachycardia

   D. Ventricular fibrillation

2. Which of the following medications have been associated with an increase in survival to hospital discharge?

   A. Amiodarone

   B. Epinephrine

   C. Lidocaine

   D. Sodium bicarbonate

3. A 68-year-old patient suddenly grabs the chest and collapses to the ground in the grocery store. After confirming the patient is nonresponsive and activating EMS through your mobile phone, what is the next best step to take as a lay rescuer?

   A. Check for a pulse

   B. Open the airway and deliver 2 breaths

   C. Perform cycles of 30 compressions and 2 breaths until an AED arrives

   D. Perform chest compressions only and omit rescue breathing.

4. Early epinephrine administration is most beneficial following which rhythm?

   A. Bradycardia

B. Pulseless electrical activity

C. Torsades de pointes

D. Ventricular fibrillation

5. The rationale for the administration of epinephrine during advanced cardiac life support measures is to increase which of the following?

A. Cardiac output

B. Coronary perfusion pressure

C. Heart rate

D. Oxygen demand

6. Randomized controlled trial data have demonstrated epinephrine to be associated with improvements in which of the following outcomes following a cardiac arrest?

A. Return of spontaneous circulation (ROSC)

B. ROSC and survival to hospital admission

C. ROSC, survival to hospital admission, and survival to hospital discharge

D. ROSC, survival to hospital admission, survival to hospital discharge, and survival to hospital discharge with good neurologic function

7. Which of the following is the drug of choice for torsades de pointes?

A. Adenosine

B. Amiodarone

C. Lidocaine

D. Magnesium sulfate

8. A 72-year-old patient presents to the ICU following the ROSC from a cardiac arrest secondary to a nonshockable rhythm. The patient did not regain consciousness and is subsequently intubated with a plan to implement targeted temperature management at 33°C (91.4°F) for 24 hours. Propofol and fentanyl infusions are prescribed for sedation and analgesia. Which adverse effect is most likely to occur upon rewarming?

A. Hyperglycemia

B. Hypokalemia

C. Hypotension

D. Prolongation of sedative medications

9. Which of the following is an acceptable therapy for asystole?

A. Amiodarone

B. Atropine

C. Defibrillation

D. Epinephrine

10. Successful resuscitation following PEA is largely dependent on

    A. Administration of thrombolytics

    B. Identification of the underlying cause

    C. Rapid defibrillation

    D. Therapeutic hypothermia

11. The postcardiac arrest care should address all of the following, EXCEPT:

    A. Hypoxic brain injury

    B. Myocardial dysfunction

    C. Systemic ischemia reperfusion response

    D. Renal impairment

12. A 79-year-old patient is admitted to the ICU following a cardiac arrest and remains comatose following the return of spontaneous circulation. The patient is subsequently intubated and sedated with a plan to implement targeted temperature management. The team would like to begin an antiseizure medication for seizure prophylaxis and asks what is the most appropriate regimen?

    A. Levetiracetam

    B. Phenytoin

    C. Valproic acid

    D. Seizure prophylaxis is not indicated

13. Which of the following is a potentially harmful effect of sodium bicarbonate?

    A. Hyperkalemia

    B. Intracellular acidosis

    C. Tachycardia

    D. Tissue hypoxia

14. Which parameter is the best indicator of high-quality CPR and most associated with ROSC following a cardiac arrest?

    A. Arterial diastolic blood pressure >15 mm Hg

    B. Arterial pH >7.2

    C. End-tidal CO_2 > 20 mm Hg (2.7 kPa)

    D. Palpating a pulse during active chest compressions

15. A 62-year-old patient presents to the ICU following a cardiac arrest secondary to an acute myocardial infarction. ROSC was achieved followed by urgent cardiac revascularization. Echocardiography reveals an ejection fraction of 60% (0.6). After 24 hours, the patient remains in a comatose state and the team is very concerned about cerebral swelling. They would like to prioritize cerebral hemodynamics and blood flow to the brain. What should the goal MAP be for this patient in the absence of advanced cerebral monitoring?

A. > 50 mm Hg

B. > 65 mm Hg

C. > 80 mm Hg

D. > 100 mm Hg

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** In general, nonshockable rhythms are associated with higher mortality rates compared to shockable rhythms. Between the nonshockable rhythms, asystole, and PEA, the survival for asystole is roughly 2% compared to 10% for PEA. This is described in the “Epidemiology” section.

2. **B.** Epinephrine has been associated with increased rates of ROSC, hospital admission and hospital survival. Survival with good neurologic function however is not improved. Both amiodarone and lidocaine have been associated with increased rates of survival to hospital admission but not discharge. Sodium bicarbonate has not been shown to increase ROSC or survival. This is described in the “Pharmacologic Therapy” section.

3. **C.** After assessing responsiveness, calling for help and activating EMS, the lay rescuer should begin chest compressions using a ratio of 30 compressions:2 breaths. If a lay rescuer is unwilling to administer rescue breaths, then chest compression-only CPR can be initiated. With arrests of prolonged duration though, arterial oxygen content will decrease if ventilations are withheld. Pulse checks are not recommended for lay rescuers because they lead to delays in the provision of chest compressions. Chest compressions should occur before ventilations consistent with the C-A-B teaching approach for CPR. This is described in the “Sequence of Resuscitation–Basic Life Support” section.

4. **B.** Early epinephrine has been shown to be most beneficial in patients with asystole or PEA. It is now a point of emphasis on current treatment algorithms. This is described in the subsection “Vasopressors” under the “VF/PVT–Pharmacologic Therapy” section and under “Pharmacologic Therapy” in the “Pulseless Electrical Activity and Asystole” section.

5. **B.** CPR provides necessary oxygen to the heart and the brain but the perfusion pressures encountered are not high enough to reach thresholds that have been associated with ROSC. Epinephrine is therefore added to increase coronary perfusion pressure through its effects on alpha-receptors. The beta-adrenergic effects of epinephrine can lead to increased heart rate, increased cardiac output, and increased myocardial oxygen demand which can be detrimental in the post-resuscitation phase. The rationale for epinephrine is explained in the subsection “Vasopressors” under the section “Pharmacologic Therapy.”

6. **C.** In a landmark randomized controlled trial (PARAMEDIC 2) comparing epinephrine with placebo, epinephrine was associated with improvements in ROSC, survival to hospital admission and survival to hospital discharge but there was no improvement in survival with good neurologic function. This was the first RCT demonstrating survival to hospital discharge with vasopressor therapy. This is described in the subsection “Vasopressors” under the section “Pharmacologic Therapy.”

7. **D.** The drug of choice for torsades de pointes is magnesium sulfate. This is the only indication for routine magnesium administration in cardiac arrest. This is listed in the “Magnesium” subsection of the “VF/PVT–Pharmacologic Therapy” section.

8. **D.** Hypothermia achieved via targeted temperature management can lead to a decrease in drug metabolism and clearance. This can largely impact sedative and analgesic medications and interfere with prognostication. Hypothermia can also lead to intracellular shifts of potassium and decreased sensitivity to insulin leading to hypokalemia and hyperglycemia. Upon rewarming, potassium is released back into extracellular compartment (increasing the risk for hyperkalemia), and insulin sensitivity increases (increasing the risk for hypoglycemia). Hypotension is not a frequent adverse event associated with rewarming. This is described in the subsection “Targeted Temperature Management” under “Postresuscitative Care”.

9. **D.** Asystole is a nonshockable rhythm that often represents confirmation of death. Therapy consists of chest compressions, epinephrine administration, and identification of the underlying cause. This is explained in the “Pharmacologic Therapy” section under PEA/Asystole.

10. **B.** Successful resuscitation of PEA is largely dependent on the identification of the underlying cause. These can be remembered using the mnemonic 6 H’s and 6 T’s. These are listed in Table 41-2.

11. **D.** The postcardiac arrest care should address hypoxic brain injury, myocardial dysfunction, systemic inflammation, and the underlying cause of the arrest. While renal impairment may be an important comorbidity and impact care delivery, it is not among the four essential elements of postcardiac care. These are described in Table 41-3.

12. **D.** While seizures can occur in the post-resuscitation phase, studies have not demonstrated a benefit with prophylactic antiseizure medications. Prophylaxis is therefore not indicated. This is further described in the "Seizures" subsection of "Postresuscitative Care."

13. **B.** Deleterious effects of sodium bicarbonate administration include intracellular acidosis, hypokalemia, tissue hypercarbia, and overshoot alkalosis. This is described in the "Acid/Base Management" section.

14. **C.** End-tidal CO_2 is a measurement of carbon dioxide excretion obtained from the lungs. As cardiac output (obtained through high-quality CPR) increases, the delivery of CO_2 from the peripheral tissues to the lungs increases. End-tidal CO_2 > 20 mm Hg (2.7 kPa) has been associated with higher rates of ROSC. Arterial diastolic blood pressure can be a surrogate for coronary perfusion pressure but goals should be > 25 mm Hg. Arterial pH and palpating a pulse during CPR have not been linked to ROSC. This is explained in the "Evaluation of Therapeutic Outcomes" section.

15. **C.** In settings where advanced cerebral monitoring is not routine and increased intracranial pressure is suspected, target MAP values that exceed 80 mm Hg may be required. This is done to increase cerebral perfusion pressure which is calculated as MAP minus ICP. In settings where advanced cerebral monitoring is performed, MAP goals can be individualized accordingly. This is explained in the "Evaluation of Therapeutic Outcomes" section.

Chapter 44: Asthma

Kathryn V. Blake; Jean Y. Moon

KEY CONCEPTS

KEY CONCEPTS

① Asthma is a highly prevalent disease that is a result of genetic predisposition and environmental interactions; it is one of the most common chronic diseases of childhood.

② Asthma is primarily a chronic inflammatory disease of the airways of the lung for which there is no known cure or primary prevention; the immunohistopathologic features include cell infiltration by neutrophils, eosinophils, T-helper type 2 lymphocytes, mast cells, and epithelial cells.

③ Chronic asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airflow obstruction from airway wall inflammation and bronchial smooth muscle constriction; in some patients, persistent changes in airway structure occur.

④ Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management. This is most evident in patients with severe asthma phenotypes.

⑤ Ongoing patient education, for a partnership in asthma care, is essential for optimal patient outcomes and includes trigger avoidance and self-management techniques.

⑥ The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids (ICS) having the greatest efficacy and safety profile for long-term management.

⑦ Acute bronchial smooth muscle constriction is prevented or treated most effectively with inhaled short-acting β_2-adrenergic receptor agonists (SABA); long-acting β_2-adrenergic receptor agonists (LABA) and long-acting muscarinic agonists (LAMA) are effective as daily maintenance bronchodilators when used in combination with ICS.

⑧ Intermittent as-needed SABA and an ICS used concomitantly in mild persistent asthma or the combination of ICS with formoterol (a long-acting β_2-adrenergic receptor agonist) used as daily maintenance and reliever therapy in moderate persistent asthma reduce exacerbation frequency.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the five short videos in the series Asthma Management Academy. These videos provide a brief overview of the following topics:

- Module 1 Scope of Asthma
- Module 2 Triggers
- Module 3 Medications
- Module 4 Medication Devices
- Module 5 Monitoring and Assessment

The videos are useful to enhance students understanding of the consequences of asthma, triggers, medications, delivery devices, and monitoring. These videos are also useful for patient education.

INTRODUCTION

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word asthma is of Greek origin and means “panting.” More than 2,000 years ago, Hippocrates used the word asthma to describe episodic shortness of breath; however, the first detailed clinical description of a person with asthma was made by Aretaeus in the second century.[1]

The Global Initiative for Asthma (GINA) provides a practical definition of asthma:[2] “Asthma is a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation.” The National Institutes of Health, National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3 (EPR3), adds that the variable airflow obstruction is often reversible either spontaneously or with treatment although reversibility may not be complete in some patients with asthma.[3] To guide our current understanding and clinical management of asthma, healthcare providers in the United States often turn to the NAEPP and GINA guidelines.

EPIDEMIOLOGY

① An estimated 25.1 million persons in the United States have asthma (about 7.8% of the population).[4] Asthma is the most common chronic disease among children in the United States affecting approximately 5 million children in 2019.[4] Self-reported asthma is more common in persons with incomes below $25,000 per year (prevalence rate 17%-20%) and among certain race and ethnic groups such as those who self-identify as multirace non-Hispanic (22.5%) and non-Hispanic Black (16.7%).[4] Adults are nearly five times more likely to die from asthma than children. The rate of death from asthma is highest in those aged 65 years and older, females, and non-Hispanic Black people (who have two to three times the death rate of non-Hispanic Whites or non-Hispanic others).[4] Biological differences in asthma factors between racial and ethnic groups have been observed (albuterol response, airway eosinophilia, low birth weight).[5–7] However, because asthma is a genetic disease strongly influenced by environmental exposures, it is not fully understood if such differences are related to environmental factors that may be tied to sociodemographic characteristics.[5,7]

Influenza infection can result in serious complications in people with asthma, even those with mild disease and those who are well-controlled on medication. An annual influenza vaccination is an essential preventative measure in people with asthma. However, in 2015, only 47% of adults and 64% of children with asthma received the influenza vaccination. A higher percentage (80%) of children under 5 years received the influenza vaccine perhaps because they are more likely to have regular visits to the pediatrician.[4]

Approximately 65% of adults and 60% of children describe themselves as having persistent (vs intermittent) asthma. However, only 40% of adults and children report using long-term controller medications that are fundamental for the prevention and control of symptoms. Nearly 20% of children and 24% of adults report using a quick-relief medication (such as an inhaled short-acting inhaled β_2-agonist [SABA]) more than twice weekly, which is a marker for poorly controlled asthma.[4]

The estimated economic costs of asthma in the United States from 2008 to 2013 in US dollars was $80 billion in direct medical expenses, missed work or school, and death.[8] The societal burden of asthma (indirect medical expenditures such as loss of productivity and death) in the United States was $33 billion. Prescription drugs were the largest single direct medical expenditure per person.[8]

The natural history of asthma is still not well defined. Although asthma can develop at any age, it is principally a pediatric disease, with most patients with asthma being diagnosed by 5 years of age and up to 50% having symptoms by 2 years of age. Asthma is more common in boys until adolescence and between 30% and 70% of children with asthma will have marked improvement or become symptom-free by early adulthood but is more common in adult women than men. Asthma persists and becomes chronic in about 30% to 40% of patients. Generally, 20% or less develop severe chronic disease.[9] Atopy, a form of hypersensitivity to allergens, is present in 50% to 60% of children and adults with asthma; it is more common in adults who had the onset of disease during childhood and children with more severe asthma.[9]

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in people with asthma when measured using forced expiratory volume in 1 second (FEV_1) and is more pronounced in those with severe disease.[9] Individuals with less-frequent asthma exacerbations and normal lung function on initial assessment have higher remission rates. Conversely, smokers have the lowest remission and highest relapse rates.[9] In those with persistent airway obstruction, asthma may become irreversible and worsen over time due to airway remodeling (described below). However, most patients do not die from disease progression and their life span is not different from the general population.

The worldwide prevalence, morbidity, and mortality from acute exacerbations of asthma have been relatively stable over the past 10 years.[10] However, those in the lowest sociodemographic groups are at a fivefold greater risk of death when compared to those in the highest sociodemographic group.[9] Most asthma deaths are preventable with appropriate recognition and treatment.[9]

Most deaths from asthma occur outside the hospital; death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airway obstruction by the patient or healthcare professional and inadequate therapy. Thus, the key to preventing death from asthma is education to both patients and providers.[11,12]

ETIOLOGY

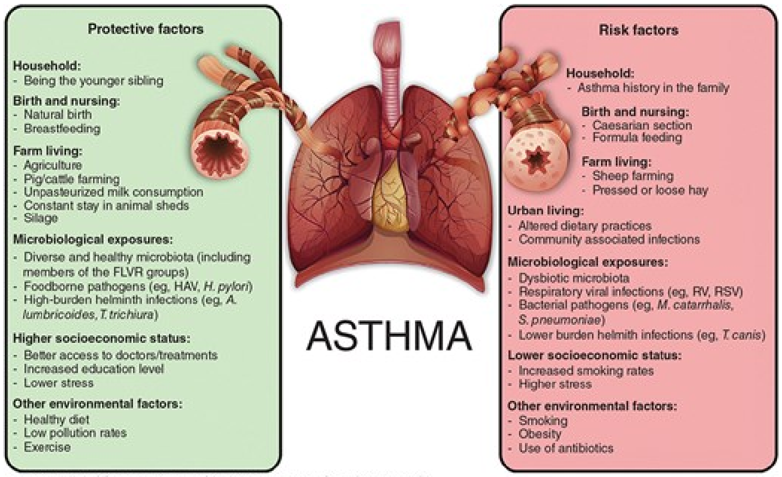
① Epidemiologic studies strongly support the concept of a genetic predisposition plus environmental interaction to the development of asthma, yet the picture remains complex and incomplete.[13] Asthma represents a complex genetic disorder, in that the asthma phenotype is likely a result of polygenic inheritance of different combinations of genes. The initial genetic research focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma. Genome-wide analyses found links with genes on multiple chromosomes that differ by racial groups.[13] Although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all patients with asthma exhibit atopy. Current efforts to identify asthma susceptibility are focused on epigenetics which are heritable characteristics that are modified by environmental influences.[13]

① Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to secondhand tobacco smoke in infancy, and in utero, allergen exposure, ambient air pollution, urbanization, viral respiratory infections including respiratory syncytial virus (RSV) and rhinovirus, and decreased exposure to common childhood infectious agents.[9] The timing of and exposure to certain environmental factors during early childhood in genetically susceptible individuals is thought to predispose them to develop allergies and asthma by triggering the allergic immunologic system (T-helper cell type 2 [Th_2] [Th_2 high asthma] lymphocytes) to develop instead of the system to fight infections (T-helper type 1 [Th_1] [Th_2 low asthma] lymphocytes).[9,14] The first 2 to 3 years of life are most important for the exposures to produce an alteration in the immune response system.[14]

Risk factors for early (less than 3 years of age) recurrent wheezing associated with viral infections include preterm birth, low birth weight, male gender, and parental smoking. However, this early pattern is due to smaller airways, and these risk factors are not believed to be risk factors for developing asthma in later life.[14] Atopy is the predominant risk factor for children to subsequently develop asthma.[14] Asthma can begin later in life in adults. Occupational asthma in previously healthy individuals emphasizes the effect of the environment on the development of asthma.[9] The heterogeneity of the asthma phenotype is most obvious when reviewing the diverse list of protective factors and risk factors (Fig. 44-1).[14] These factors have relative degrees of importance. Environmental exposures are the most important precipitants of severe asthma exacerbations. Epidemics of severe asthma in cities have followed exposures to high concentrations of aeroallergens. Viral respiratory tract infections remain the single most common precipitant of severe asthma in children and are an important trigger in adults as well.[15] Other factors precipitating asthma exacerbations include air pollution, emotions, exercise, occupational exposures, and drugs.

FIGURE 44-1

Factors that are associated with protecting against, or risk for, developing asthma. These various factors have relative degrees of importance from patient to patient. (*Reprinted from van Tilburg Bernardes E, Arrieta MC. Hygiene hypothesis in asthma development: Is hygiene to blame? Arch Med Res. 2017;48(8):717–26.*)



Protective factors
Household:
- Being the younger sibling
Birth and nursing:
- Natural birth
- Breastfeeding
Farm living:
- Agriculture
- Pig/cattle farming
- Unpasteurized milk consumption
- Constant stay in animal sheds
- Silage
Microbiological exposures:
- Diverse and healthy microbiota (including members of the FLVR groups)
- Foodborne pathogens (eg, HAV, H. pylori)
- High-burden helminth infections (eg, A. lumbricoides, T. trichiura)
Higher socioeconomic status:
- Better access to doctors/treatments
- Increased education level
- Lower stress
Other environmental factors:
- Healthy diet
- Low pollution rates
- Exercise
ASTHMA
Risk factors
Household:
- Asthma history in the family
Birth and nursing:
- Caesarian section
- Formula feeding
Farm living:
- Sheep farming
- Pressed or loose hay
Urban living:
- Altered dietary practices
- Community associated infections
Microbiological exposures:
- Dysbiotic microbiota
- Respiratory viral infections (eg, RV, RSV)
- Bacterial pathogens (eg, M. catarrhalis, S. pneumoniae)
- Lower burden helmith infections (eg, T. canis)
Lower socioeconomic status:
- Increased smoking rates
- Higher stress
Other environmental factors:
- Smoking
- Obesity
- Use of antibiotics
